Blunt trauma accounts for the vast majority of presentations, with motor vehicle accidents the commonest mechanism of injury. The last decade, however, has seen a worrying rise in inflicted lethal penetrating injury. This has manifested as rises in knife crime in the United Kingdom and firearm-related harm in the United States of America. Paediatric firearm-related mortality in the US recently exceeded motor vehicle mortality as the leading cause of death amongst children and adolescents. [2]

Children in conflict zones around the world present markedly different patterns of injury. Data from the United States Department of Defence Trauma Registry identified that 22% of children present with gunshot wounds, while 43% are injured by explosions. [3]

Patterns of trauma have changed over time, as have patient outcomes. Key drivers of improved outcomes over several decades include legislation to improve safety on roads, in workplaces and in homes (e.g. seatbelt laws, drink-driving laws, health and safety legislation and laws governing such domestic risks as pool fencing and the fitment of smoke detectors). In tandem, considerable innovation within healthcare has led to improved outcomes for trauma patients across the care continuum, from the point of injury onward. These include:

- Standardised trauma education courses (e.g. advanced trauma life support, early management of severe trauma and stop the bleed).
- Rapidly available, high-quality pre-hospital clinical capability.
- Development of institutional trauma team models with rapid, multidisciplinary responses.
- Database development and the ability to benchmark performance.
- Accredited regional trauma centres with defined levels of capability.
- Streamlined referral and retrieval systems.

How does paediatric trauma differ from that seen in adults?

Patterns of injury are dictated by several factors. It is also the case that within the paediatric age group, injury patterns vary with age and developmental stage. Where relevant, specific organ-system differences will be highlighted later in the chapter. General considerations however include:

Developmental stage: Infants become increasingly mobile and capable in their first year of life, with relevant milestones including: rolling between 3 and 5 months and walking around 9–12 months. Risks at this age include falls and non-accidental injury. Toddlers from 1 to 3 years are mobile with developing climbing skills, but they lack the ability to competently assess risk. Outside the home, roads and bodies of water present serious hazards, while inside the home kitchens, stairs and bathrooms are risks. Pre-school and primary school-age children are becoming increasingly capable and adventurous. Activities such as cycling, horse-riding, scooters (including electric) and climbing become common, while parental supervision levels typically decline as children get older. From secondary school age onward, adolescent risk-taking behaviour increases, as does self-harm, assaults and the potential for workplace-related injuries. The latter years of childhood have injury patterns approximating those seen in young adults.

It should be noted that the ability to elicit a history or meaningful examination from children varies significantly by age and developmental stage.

Anatomical differences: Injury patterns can vary by patient height. For example, an adult struck by a car will sustain injuries to lower limbs and pelvis from direct impact. There may be upper body, face or head injuries thereafter when the patient flexes and strikes the bonnet or is propelled. A toddler struck by the same vehicle, however, will be directly impacted from pelvis to head.

Body proportions change with age, with younger children having an increased ratio of body surface area to mass. This alters the calculation of burn surface area. It also means that children become cold rapidly, and particular care is required to minimise heat loss.

Physiological differences: Compared to adults, children are better able to compensate haemodynamically for blood or fluid loss. Early deterioration can be subtle and is easily missed. Detection of subtle deterioration is improved by an awareness of normal physiological observations for age and tracking serial observations over time. Several age-specific paediatric observation charts exist with this functionality, and typically institutions or regions will have their preferred standardised tool.

The development of ‘Trauma Teams, Centres and Services’

The concept of multidisciplinary teams and institutions with specific interests and expertise in trauma management began to develop in the 1950s and 1960s. [4] Currently, most developed countries have accreditation processes for trauma services and designate different centres by ‘level’ based on their capabilities.

In addition to doctors and nurses from acute specialities such as the emergency department, surgical subspecialities, anaesthesiology and critical care, the wider multidisciplinary team frequently includes trauma coordinators, research staff and rehabilitation specialists such as physiotherapists, psychologists and social workers. Similarly, the remit of trauma teams, centres and services has expanded beyond simple care of the traumatised patient and now includes data collection and analysis, development of injury-prevention strategies and co-ordination of regional trauma services.

There is growing evidence that development of trauma teams, centres and services improve outcomes for injured adults [5] and children. [6] Opinion is more divided on whether or not outcomes for seriously traumatised children are improved when managed in designated paediatric trauma centres compared to adult trauma centres. [7], [8]

Specific Paediatric Trauma Presentations

Differing mechanisms of injury may be associated with specific patterns of injury in both children and adults, though anatomical and physiological differences between age groups will alter the pattern seen. Children requiring intensive care unit admission will have serious injury to one or more of the following systems.

Traumatic Brain Injury (TBI)

Brain injury, resulting either directly from trauma or indirectly from hypoxic-ischaemic insult, accounts for the majority of death and long-term severe morbidity in paediatric trauma. Once the primary injury has occurred, management is entirely focused on prevention of secondary insults and further damage. Conventionally this involves control of intracranial hypertension, defence of cerebral perfusion pressure (CPP) and mitigation of injurious factors such as seizures, hypo- or hyperglycaemia, hypoxaemia and fever. An overview of this topic is provided below, but those wishing a comprehensive review of the current evidence base behind the current management of paediatric TBI are directed to guideline documents published by the Brain Trauma Foundation. [9]

Paediatric TBI: Anatomical and physiological considerations

Adult brain volume is reached around six years of age, whereas skull growth continues until around sixteen years of age. Children thus have less room for brain swelling within the rigid skull than adults. This is compounded by differences between children and adults in adaptive mechanisms to defend against raised intracranial pressure (ICP), including smaller relative cerebrospinal fluid volumes, higher intracellular concentrations of sodium and impaired ability of neurons to extrude sodium. In addition to the propensity of smaller children to raised ICP, CPP may be further compromised by the similarities in autoregulation of cerebral blood flow between small and larger children, affording smaller patients less safety margin. [10]

Neurological assessment and monitoring of children

Priorities of the assessment process are as follows:

- To benchmark neurological function over time
- To identify lesions and problems requiring treatment
- To identify prognostic markers

Neurological assessment of the injured child requires an appreciation of child development and may be facilitated using age-appropriate tools (such as a modified Glasgow coma score). Assessment is best done as a process involving frequent clinical assessments over time supplemented where indicated by targeted investigations such as computed tomography (CT) or magnetic resonance imaging (MRI).

Invasive monitoring of ICP and arterial blood pressure allows identification of deleterious ICP and permits calculation of CPP.

ICP monitoring should be zero-calibrated at the tragus of the ear with the patient inclined 30 degrees. The target ICP threshold requiring management has not been defined in paediatrics, but current evidence would support an upper value of 20 mmHg. Lower values of 15-20 mmHg may be more appropriate for small infants.

CPP is defined as *mean arterial pressure – mean ICP* . Mean arterial pressure should be zero-calibrated at the level of the right atrium with the patient inclined at 30 degrees. It should be noted that the difference in zero level between ICP and MAP will not give a true CPP as stated and that the error will increase with increasing patient length. It does, however, allow for standardisation of measurement within routine clinical practice. Target CPP thresholds requiring management have not been defined in paediatrics, but current evidence would support a CPP target of between 40 and 50 mmHg.

Management priorities in the child with head injury

Management of paediatric neurotrauma focuses on minimising secondary injury to neurons. Principles include the following:

Management of intracranial pressure: This involves manipulation of intracranial contents as described in the Monro-Kellie hypothesis. Thus the intracranial volume lying within the incompressible skull is composed of brain tissue, blood and cerebrospinal fluid (CSF), and any increase in the volume of one of the components must be compensated for by a reduction in volume of the others or pressure will increase. Interventions manipulate the following volumes as follows:

- **Blood compartment:** Decreasing intracranial blood volume may be tackled in three ways.
    - Extravasated blood: Significant collections require surgical evacuation.
    - Venous compartment: Optimise venous drainage by minimising venous obstruction (spinal collar, internal jugular lines, excessive PEEP) and patient positioning (30 ° head up, head midline). One small paediatric study demonstrated that an increased head-up bed angle decreased ICP but not CPP. [11] Judicious sedation and muscle relaxation decrease the

incidence of coughing, shivering and asynchrony with mechanical ventilation.

- Arterial compartment: Manipulation of this compartment requires brain tissue with preserved autoregulation to pCO_2, pH, viscosity and metabolic demand. Mild hyperventilation vasoconstricts these areas, thereby decreasing the volume of the arterial bed. Prolonged or extreme hypocarbia should be avoided due to the potential for cerebral ischaemia, particularly in vulnerable penumbral areas of the injured brain. Hypercarbia must also be avoided as it will increase ICP. Volume-controlled ventilation may permit more stable $PaCO_2$ control than pressure-control ventilation.
    - Osmotic agents such as 3% (hypertonic) saline or mannitol exert a rheological effect by dehydrating red blood cells. The resultant decrease in blood viscosity permits a degree of cerebral vasoconstriction while still meeting metabolic demands. Use of hypertonic saline in preference to mannitol appears better supported in the literature to date.
    - Decreasing neuronal metabolic demand can lower ICPs. Seizures should be controlled and hyperthermia avoided. Beyond that, second-tier therapies such as barbiturates and therapeutic hypothermia (32–33°C) have been demonstrated to decrease refractory raised ICP. Both have potential serious side effects and limited evidence to support routine use. Recent randomised controlled trials of therapeutic hypothermia *vs.* normothermia in children have failed to demonstrate differences in functional outcome, and either no difference in mortality [12] or a trend towards increased morbidity and mortality in the cooled group. [13] A further study,

Cool Kids, was stopped early on grounds of futility.

- **CSF volume:** External ventricular drainage of the lateral ventricles allows a decrease in CSF volumes in addition to ICP monitoring, though may not be practical if the ventricles have already been effaced.
- **Brain volume:** Osmotherapy with hypertonic saline or mannitol may decrease intracranial volume by dehydrating neurons in areas with an intact blood- brain barrier.

A fourth mechanism for decreasing ICP is to undertake a decompressive craniectomy. While randomised controlled trial data in adults demonstrated decreased ICPs in patients receiving this intervention, the operated group experienced either mildly improved [14] or worse outcomes. [15] In paediatrics, while several small studies have demonstrated the utility of decompressive craniectomy in reducing raised ICP, evidence of effect on outcomes is lacking. [9], [16]

Prognostic markers in head injury have been identified. These include Glasgow coma scale score, injury severity score and initial hypotension. [17] Of note, the motor score component of the Glasgow coma scale may be as predictive as using the entire score. [18]

Thoracic trauma

Anatomical and physiological considerations

The immature ribcage is largely cartilage and ossifies through childhood. Compliant ribs allow transmission of greater impact energy to underlying viscera, allowing severe contusion without necessarily fracturing. Furthermore, the compliant infant chest and relatively transverse ribs impair tolerance of upper airway obstruction.

Increased basal metabolic rate and reduced functional residual capacity result in a more rapid onset of hypoxaemia in younger children, and this may be compounded in infancy by physiologically low haemoglobin.

Assessment and management of thoracic trauma

Immediate assessment of a child with thoracic trauma is focused on identifying life-threatening injuries, which include:

- Large airway disruption
- Tension pneumothorax
- Open pneumothorax
- Massive haemothorax
- Flail segment
- Cardiac tamponade

Management is guided by the specific findings from the primary survey, but severe thoracic trauma is likely to require intubation and ventilation, with pleural or pericardial drainage as indicated. Rare but severe injuries that may be difficult to detect during resuscitation and therefore require a high index of suspicion would include major vascular injuries, thoracic spinal injuries and traumatic diaphragmatic hernia.

Ventilatory tidal volumes of 6–10 mL/kg are reasonable initial settings across all paediatric age ranges, with inspiratory times typically 0.5–1 second.

A chest X-ray is a component of routine trauma assessment, supplemented as indicated by ultrasound assessment and CT. Angiography of the great vessels may be undertaken formally or as part of the CT scan. Serial arterial gases guide requirements for ventilatory support

Abdominal Trauma

Anatomical and physiological considerations

The orientation of the compliant ribs in small children affords less protection to the disproportionately large liver and spleen when compared to older children or adults, while the shallow pelvis leaves the bladder at similar risk.

Little children are difficult to examine. They are also prone to aerophagia with distension of the stomach increasing emesis risk and in some cases leading to diaphragmatic splinting.

Paediatric abdominal trauma is largely blunt in nature, with solid organ injury occurring far more commonly than hollow visceral injury. Certain mechanisms of injury should lead to the suspicion of characteristic injuries. These include handlebar into epigastrium associated with pancreatic or duodenal injury, lap-belt injuries in motor vehicle accidents leading to small bowel rupture, diaphragmatic injury or Chance fracture of the lumbar spine. Given the difficulties in diagnosis, a high index of suspicion for abdominal injuries should be maintained in traumatised children.

When suspicion of abdominal injury exists, repeated clinical examination over time is supplemented by plain abdominal X-rays, ultrasonography or CT scanning as indicated. In haemodynamically stable blunt paediatric trauma, focused abdominal sonography for trauma (FAST) currently lacks the sensitivity and positive-predictive power to be used as a definitive screening tool. [19] At the present time, CT scanning of the abdomen is considered ‘gold standard.’

In most paediatric trauma involving the abdomen, management is expectant. Laparotomy is generally reserved for the following situations:

- Penetrating injury
- Hollow viscus perforation (bladder rupture/pneumoperitoneum)
- Haemodynamic instability despite adequate fluid resuscitation (≥40 ml/kg)
- Peritonism (later sign)
- Diaphragmatic rupture

Even high grades of splenic or hepatic laceration may be managed conservatively, provided assessment is frequent and the patient is managed in a facility with the ability to intervene surgically at short notice.

Spinal Injury

Spinal injury in children is rare, often difficult to diagnose and potentially devastating if missed. Anatomical and physiological differences between adults and children change injury patterns while adding to the difficulties in clinical assessment and radiological interpretation. Furthermore, as spinal injuries are rare, the benefits of managing injured children in a paediatric facility must be balanced against the expertise available in adult spinal injury centres.

Anatomical and physiological considerations

Differences in the immature spine and proportionally more massive head change injury patterns when compared with adults. High lesions from the occipitoaxial junction to C3 are more common than the more typical C4-C5 lesions seen in older patients. In addition, the elasticity of paediatric ligaments may lead to the phenomenon of spinal cord injury without radiological abnormality (SCIWORA), present in 17%–43% of paediatric cord injuries.[20], [21]

Mechanisms of injury change at different stages of development, with an increasing incidence of sports injuries prevalent in older children.

Preverbal children present challenges in assessment and even older children may regress and become uncompliant with clinical examination. Additionally, progressive ossification of the spine during childhood renders radiological interpretation problematic.

Spinal cord injury in children, particularly when very young, leads to an increased incidence of scoliosis, tracheostomy (due to the increased incidence of high lesions) and progressive pulmonary insufficiency.

Assessment and Management

The possibility of spinal cord injury should be considered in all significant trauma, and particularly following motor vehicle accidents, rapid deceleration injuries or in the presence of multisystem trauma, head injuries, other injuries above the clavicle or abnormal neurological signs.

The priority is spinal immobilisation, which should occur in the pre-hospital phase. Current practice involves avoidance of unnecessary neck movement, supplemented by sandbags or manual in-line stabilisation. Use of hard collars is no longer recommended.

Clinical assessment is supplemented by plain radiography in the initial assessment. In severely traumatised patients, early neck clearance by clinical examination is not possible and even plain radiography in three views, which has 94% sensitivity, will fail to detect SCIWORA. CT and MRI contribute additional information but still will not detect all lesions, even when motor signs are present.[22]

Spinal precautions must be maintained until either the neck is deemed to be uninjured or stable on clinical and radiological grounds or until fixation has occurred.

Use of steroids or hypothermia in paediatric spinal injury is not supported by evidence currently and is not regarded as a mainstream therapy.

Early feeding, gastric protection with proton-pump inhibitors, bowel care, care of skin and pressure points and prevention of contractures are important interventions if not precluded by other injuries. Similarly, early access to rehabilitation services may improve functional outcomes.

Burns

Burns are a common cause of accidental death in childhood. Younger children predominantly suffer from scalds, while older children are more likely to present with flame burns. Burns are often included within the extended scope of trauma as many mechanisms leading to burns are also associated with traumatic injury (motor vehicle accidents, explosions etc.). Additionally, when confronted by the prospect of burning, patients will frequently risk or incur traumatic injuries during attempted escape.

Anatomical and physiological considerations

The increased surface area/weight ratio of children compared to adults leads to a number of problems. Fluid loss from the burn may rapidly lead to dehydration, and any surface cooling undertaken increases the risk of iatrogenic hypothermia. Furthermore, alterations in body proportions from birth to adulthood mandates the use of specific methods for estimating paediatric burn surface area such as the modified Lund and Browder chart. Estimated burn surface area may be made using the area of the child’s palm with outstretched fingers. Each such area corresponds to 1% of body surface area (areas of erythema should not be included in estimation of burn surface area).

Mechanisms of injury and patterns of burn are different for adults. Small, curious children below the level of kitchen work surfaces are commonly scalded on the face, head and upper body when pulling pans and kettles down, an injury exacerbated by a disproportionately large head. Similarly, severe hand injuries may follow attempts to grasp hot objects, or in older children, fireworks.

The small paediatric airway is particularly vulnerable to upper airway obstruction following smoke inhalation.

Finally, paediatric burn injury may result in profound and progressive disability. Thick burn scarring may distort normal somatic growth, and psychological scarring may severely compromise social development.

Initial management

First aid for burns involves cooling for not longer than twenty minutes, using tepid (not cold) water. As burns and trauma frequently coexist, a trauma primary survey (Airway + cervical spine control, Breathing, Circulation, Disability) should be rapidly carried out. The findings of particular relevance are listed in Box 97.1 .

Box 97.1

Primary survey findings in burns

Airway: Is there actual or impending airway compromise?

- History of burn in enclosed space.
- Facial burns/swelling.
- Stridor or respiratory distress.
- Carbonaceous sputum.

Breathing: Is there respiratory compromise?

- Respiratory distress.

- Cyanosis.
- Thoracic or upper abdominal burns.
- Circumferential thoracic burns.

Circulation: Is there evidence of hypotension or hypovolaemia?

- Calculate burn surface area, ascertain time of injury to facilitate fluid management.
- Shock from associated injuries?

Disability (neurology): Is there impairment of conscious level?

- Carboxyhaemoglobin level?
- Other toxins from smoke, e.g. cyanide?
- Associated head injury?

Once cooled, burns should be covered with sterile, non-occlusive dressings. Creams or ointments should not be applied unless advised by the local burns surgeon. Adequate hydration is required to optimise perfusion of injured areas. Fluid regimes such as the Parkland, Brooke or Galveston formulae (or modifications thereof, see Box 97.2) are routinely initiated.

Box 97.2

Modified Parkland formula

Patients require resuscitation fluids + maintenance fluids

Resuscitation fluids: 3–4 mL Hartmann’s solution × weight (kg) × %total body surface area burned.

Half of this volume is given in the first 8 hours from time of injury, with the remainder given over the subsequent 16 hours.

Maintenance fluids (commonly Hartmann’s + 5% dextrose): 100 mL/kg/day for the first 10 kg, 50 mL/kg/day for the next 10 kg then 20 mL/kg/day for every kg thereafter.

- Formula is used in burns exceeding 15% of total body surface area.
- Fluid boluses given during resuscitation may be subtracted unless pre-existing dehydration or associated injuries exist.
- Aim is for *adequate* urine output: 1–2 mL/kg/h < 30 kg, 0.5–1 mL/kg/h >30 kg

Pain relief with opioids and consideration of need for escharotomy where burns are circumferential should occur early and repeated frequently as required.

Definitive care

Major burns are best managed by burns centres. Burned patients in the ICU are commonly ventilated for inhalational injury or to facilitate pain management. These patients require meticulous attention to fluid and electrolyte balance, nutrition, analgesia and wound care. Frequent trips to the operating room for dressing changes, wound debridement or skin grafting are expected. Routine antibiotics are not indicated, but patients require close monitoring for signs of evolving sepsis. Wound swabs and cultures of debrided tissue assist in surveillance for sepsis.

Non-Accidental Injury

A proportion of children presenting with trauma will have been injured deliberately or through neglect, often by a parent or caregiver. While confronting, non-accidental injury is an important diagnosis to consider as it has profound implications for the future safety of both the affected child and the family at large. In many countries, there is an obligation for healthcare practitioners to report concerns to child protective services.

While presentations are highly variable and may be covert, there are a number of risk factors that may increase the likelihood of an injury being factitious as follows:

Injury characteristics:

- Delayed presentation of injury
- Injury inconsistent with history provided
- Injury inconsistent with child's developmental stage
- Injury with suspicious pattern as follows:

  Bruising
    - – Specific patterns, e.g. belt buckle, handprints, loop-marks from flex
    - – Multiple bruises of differing ages

  Fractures
    - – Fractures of different ages.
    - – Specific patterns, e.g. spiral humeral fracture.

  Burns
    - – Specific patterns, e.g. immersion (glove/stocking/thighs, sometimes sparing buttocks and backs of knees), cigarette or cooker top.
    - – Burns of different ages.

  Others
    - – Retinal haemorrhages.
    - – Bite marks.
    - – Bleeding from, or trauma to anus or genitalia.

In addition to features of the injury, there are numerous patient and social factors increasing the risk of factitious injury which include amongst others:

Patient factors: Young age, congenital anomalies, physical or intellectual disability, adoption etc.

Social factors: Young or single parents, unstable family situations, substance abuse and parents who were themselves abused. Environmental stresses include divorce or financial/legal/professional difficulties.

Summary

Paediatric trauma is common and associated with a vast burden of morbidity and mortality. While it differs in important respects from trauma in adults, the application of good basic care combined with an understanding of relevant anatomical, physiological and pathophysiological factors would be expected to improve outcomes. The development of local or regional dedicated Paediatric Trauma Teams or Services appears to be associated with improved outcomes and represents a powerful mechanism for developing and disseminating regionally appropriate protocols, undertaking research and engaging legislators. They also typically serve as a first point of call to render assistance in the event a child presents with trauma.

Paediatric treatment limitation and organ donation

Sainath Raman, Helen Miles and Tina Anne Coco

Introduction

Due to improving knowledge and medical care, an increasing number of children are surviving longer with life-limiting illnesses and complex comorbidities. The care of these children throughout their lifespan frequently necessitates support in an intensive care environment. Whilst infant and child mortality rates have declined both inside and outside of the hospital, the paediatric intensive care unit (PICU) is still the location of death for most children who die in hospital. [1] Approximately 70% of deaths in PICU, whether due to a new illness or a complication of a longstanding one, occur after withdrawing or limiting life-sustaining treatment. [2] Care of a paediatric patient and their family has, by its nature, many differences to adults. These include differences in age-related physiology, emotional and social requirements/norms and the legal framework that supports decision-making for children around end-of-life care. This chapter aims to explore these nuances as they pertain to decision-making for withdrawal and limiting life-sustaining measures, provision of end-of-life care and organ and tissue donation.

Withdrawal and Limitation of Therapy

The decision-making that underlies the redirection of care from active curative intent to comfort requires mutual agreement between a patient's parents (or guardians) and clinicians. This transition of care is often more complex emotionally, ethically and legally compared to similar scenarios involving adult patients. The legal framework, providing guidance around how these decisions and transitions occur is based on a historical ‘prerogative’ known as the parens patriae power. Parens patriae power is the doctrine that grants the ‘state’ or court the power to protect persons who are legally unable to act on their own behalf. How this is applied is defined through case or ‘common’ law. It relies on key principles that determine the ‘best interests of the child’, including quality of life, medical futility and the balance of burden versus the benefits of treatment. As for adults, the involvement of the child themselves in the decision-making process, where the situation permits, is fundamental to considering the ‘best interests’ of the child.

Legal Framework and Case Law

Occasionally disputes arise where clinicians and families might have differing views on the management pathway for the child. Judgements in courts that determine these disputes constitute the ‘common law’. Similar to the jurisprudence in Britain, various Australian state and territory courts have the power to hear disputes that revolve around withholding or withdrawing life-sustaining treatment. The statues that guide these decisions are the Children Act 1989 (UK) and the Family Law Act 1975 (Australia). The courts use the principle of ‘best interests of the child’ to decide the threshold at which to intervene as well as the approach. With recent high-profile cases such as Gard and Evans, these justifications have been challenged in the media and scientific literature. [3]

The judgements in common law cases about withholding or withdrawing life-sustaining treatment establish the legal basis for the limitation of medical treatment.

Certain clinically relevant legal requirements in this setting that are presumed include:

- limitations of treatment are omissions, not acts
- withholding and withdrawing treatment are legally equivalent

- sedation or analgesia may be administered with the purpose of relieving pain, suffering and distress, but it may also unintentionally shorten life
- although ethical standards and clinical guidelines are not legally enforceable, adherence to these may be scrutinised by courts in the context of meeting an appropriate standard of care.

Quality of Life

That the future quality of life could be considered a factor in a decision to withhold treatment was foreshadowed in the case of Baby M in Australia. [4]

Baby M

Although the coroner's court does not create binding common law, this case illustrates some of the principles that the supreme courts may consider. This case concerned an infant born with a severe spina bifida with a large lumbar myelomeningocele, hydrocephalus, Arnold–Chiari malformation of the brainstem, vocal cord paresis and severe deformities of the lower limbs. She was relatively unresponsive, had little spontaneous movement and had difficulty swallowing, sucking and breathing. If she survived, she would be unable to walk, be doubly incontinent, have no sexual function, probably require an artificial airway and would certainly require multiple operations on her spine and lower limbs. Her quality of future life was estimated extremely poor. Accordingly, the medical staff of the hospital and parents decided that no active treatment, including surgery to close the myelomeningocele, be undertaken. Feeding was restricted to that on demand and she was given paracetamol and phenobarbital. Subsequently, she developed respiratory difficulty, was treated with an infusion of morphine and died 12 days after birth. However, a member of the 'Right-to-Life' association complained to police about the infant's treatment. An autopsy was performed. The deputy coroner found that the infant had died of natural causes secondary to bronchopneumonia and hypoxia secondary to vocal cord paralysis obstructing the upper airway obstruction in the presence of toxic amounts of phenobarbital and morphine.

The case focused on the validity of withholding medical treatment in circumstances based on the *quality of life* . The deputy coroner, whilst noting that quality of life factors are not generally valid reasons to withhold treatment, found that the very serious disabilities of Baby M placed her in a group that would not be selected for surgery. Medical staff involved in the case was exonerated by the deputy coroner who stated that their decisions were legally, ethically and morally sound.

Baby D

Baby D [5] who had been born at 27 weeks' gestation and required intubation and mechanical ventilation whilst a twin developed normally. Several extubation attempts were unsuccessful over several months. At one re-intubation, hypoxaemia caused cardiac arrest requiring external cardiac compression. A subsequent magnetic resonance imaging scan revealed major hypoxic brain damage that was expected to result in severe cerebral palsy and blindness. However, she was conscious and had intact brainstem function and intact cardiorespiratory function except for life dependence on intubation. Her parents applied to the Victorian State court to allow extubation (withdrawal of therapy) without re-intubation if airway obstruction re-occurred. The court authorised the withdrawal of therapy on the basis that continuation of life-maintaining treatment would result in a very poor quality of life, which was therefore not in her best interests. The principle of the 'double effect' of appropriate use of sedative agents to allay suffering but inevitably shortening life was also affirmed.

Although this case illustrates the principle of quality of life that may be considered by the courts, the way the principle is applied may vary, depending on the patient's circumstances. In a case of disability following an accident, as opposed to one of disability from birth, a perception by the child of what has been lost, rather than never known, may be relevant to judging the quality of life.

Re Wyatt

This was a case heard in the High Court of Justice in England in which the parents of a severely disabled infant and her doctors could not agree on what would be considered appropriate treatment should the infant's condition deteriorate.[6] This case defined the role of a court order in subsequent medical management and re-examined the meaning of ‘best interests’.

At the age of 1 year, Charlotte Wyatt, who was born at 26 weeks gestation with microcephaly and profound brain damage, was blind, deaf, incapable of voluntary movement or response and had severe spastic quadriplegia. Additionally, she had irreparable chronic lung damage dependent on supplemental oxygen and had kidney dysfunction that would require dialysis. The doctors wanted to withhold mechanical ventilation after extubation. Parents disagreed. Following this dispute between the infant’s parents and doctors, a court order was made that doctors could withhold mechanical ventilation otherwise necessary to prolong life, on the grounds that to do otherwise was not in the infant’s best interests. When the infant attained the age of two years, the parents re-applied to the court to have the previous declaration set aside on the grounds that she had improved. Whilst Justice Hadley discharged the declaration, he made it clear that the child’s parents could not insist on a treatment (in this case ventilation) be provided where the requested treatment ‘is inimical to the best interests of the patient and that the professional conscience, intuition or hunch confirms that view. … may refuse to act and cannot be compelled to do so, though he should not prevent another from so acting should that clinician feel able to do so’.

Futility

Futility is difficult to define and may be quite different according to the perspectives of parent and physician, as illustrated in the matter of Baby K,[7] when doctors, opposed by the mother, sought to discontinue mechanical ventilation for an anencephalic infant solely on the basis of futility. From a purely medical standpoint, there is agreement from many UK and European medical societies, that this term does not fully encompass what is understood colloquially by the term. It has been proposed that the term futility applies to treatments that will not achieve a physiological goal. The recommendation is that the term ‘potentially inappropriate’ or ‘inadvisable’ treatment be employed instead as it would include both ‘futile’ treatments but also those treatments which are not in the best interests of the patient based on ethical and value judgements of the treating team. This terminology is also recommended as it may help communication between a surrogate decision maker and the treating team and hopefully avoid the rare occasion where the courts are required to be involved in these decision-making processes.

Airedale NHS Trust v Bland

Withdrawal of treatment from persons in persistent vegetative state (PVS) came to legal notice in Britain in 1993 in the case of *Airedale NHS Trust v Bland* .[8] The physicians attending to Anthony Bland, a young man in PVS after being asphyxiated in a crowd stampede, proposed cessation of artificial feeding and withholding of antibiotic therapy in case of infection. These actions would culminate in his death by starvation and, although unpleasant for hospital staff, would not cause discomfort or stress to the patient. His 'best interests', it was argued, would be to lawfully discontinue all life-sustaining treatment and medical support.

In that case, the House of Lords was unanimous in affirming the declarations that permitted the physicians to end the young man's treatment. Lord Hoffmann's reasons indicated that not only the interests of the patient but also the family's needs may be important too:

'in the extraordinary case of Anthony Bland, we think it more likely that he would choose to put an end to the humiliation of his being and the distress of his family. Finally, Anthony Bland is a person to whom respect is owed and we think that it would show greater respect to allow him to die and be mourned by his family than to keep him grotesquely alive'.

Similarly, Lord Mustill delivered comprehensive and clear statements related to the benefits to be gained by different parties. It was in the best interests of the community that Anthony Bland be allowed to die:

'it is the best interests of the community at large that Anthony Bland's life should now end. …. The stress of the family will get steadily

> *worse. The strain on the devotion of a medical staff charged with the care of a patient whose condition will never improve will continue to mount. The large resources of skill, labour and money now being devoted to Anthony Bland might in the opinion of many be more fruitfully employed in improving the condition of other patients, who if treated may have useful, healthy and enjoyable lives for many years to come.'*

Although the decision still focused on Bland's best interests as determinative (as opposed to that of the patient's family), their Lordships framed the legal question in the positive rather than the negative. In other words, rather than asking whether it is in the best interest of the patient to discontinue treatment, the question became whether it was in the best interest of the patient to continue life-sustaining treatment. [9]

Messiha v South East Health

This Australian case involved a 75-year-old man in a deep coma with absent cortical activity several days after sustaining a hypoxic–ischaemic injury during asystolic cardiac arrest. [10] Physicians proposed withdrawing mechanical ventilation, which would culminate in his death earlier than if treatment was continued. This was opposed by family members. In this case, the NSW Supreme Court declined to exercise its parens patriae jurisdiction to prevent withdrawal of treatment because, the judge agreed, continued treatment would be futile, as had been found to be the case by the treating practitioners.

Burdens Versus Benefits

Sometimes the American courts have treated the 'best interests' inquiry as involving the weighing of burdens versus benefits. This was described clearly by the judgement in *In the matter of AB* [11] in which an American court ruled, upon a request from a mother, that treatment could be withdrawn from her 3 ½-year-old child who had sustained hypoxic brain damage secondary to a cardiac arrhythmia. The decision hinged on the 'best interest' standard, which was said to 'require a weighing of the benefits and burdens of treatment options including non-treatment as objectively as possible. As the court stated, ‘Factors that should be considered when making decisions about life-sustaining or life-saving treatments for a seriously ill newborn include: (1) the chance the therapy will succeed, (2) the risks involved with treatment and non-treatment, (4) the degree to which the therapy if successful will extend life, (5) the pain and discomfort associated with the therapy and (6) the anticipated quality of life with and without treatment’.

Benefit versus burden was also the issue in the British case of *An NHS Trust v B* [12] – a case in which doctors wanted to withdraw mechanical ventilation, against the wishes of parents, from an 18-month-old child who had spinal muscular atrophy (SMA) type I. The child’s illness had progressed to the point where the only spontaneous movement possible was that of eyebrows. The case is notable for three reasons. First, the court drew up an extensive list of burdens and benefits specific to the child that serve as a good illustration of factors needing consideration in an individual case. Second, although the burdens appeared to heavily outweigh the benefits and hence favoured discontinuation of treatment, Judge Holman ruled in favour of continuing mechanical ventilation via endotracheal intubation. Third, Holman also ruled against the need for a tracheostomy, this created a difference between withdrawing treatment (cessation of mechanical ventilation) and withholding treatment (tracheostomy).

This astounding decision attracted considerable media attention in Britain as it was not consistent with previous case law. For example *Re C* a 16-month-old ventilated child with SMA type I, in which the judicial decision was to allow the withholding of mechanical ventilation against parental wishes in the event of a future respiratory arrest once the present mechanical ventilation had been successively weaned. [13] Additionally, another case – *Re K* [7] – in which the court ruled that it was appropriate to cease parenteral nutrition in an infant with congenital myotonic dystrophy who had recurrent episodes of sepsis secondary to central venous access that required ventilation.

The judge distinguished the circumstances in the case of *NHS Trust v B* on the basis of the child’s age and development.

Mohammed’s Case

The New South Wales case of *TS & DS v Sydney Children's Hospital Network* ('Mohammed's case')[14] was determined on the basis of an assessment of burden over benefits in determining a child's best interests. The parents applied to the Supreme Court of New South Wales for an order that invasive mechanical ventilation for their 9-month-old infant with a severe neurodevelopmental disorder due to pyruvate dehydrogenase deficiency be continued. Unfortunately, due to the underlying disease, Mohammed sustained a prolonged period of hypoxaemia. This resulted in the infant being unresponsive, develop seizures, blindness, deafness and cardiac failure requiring continuous positive airway pressure. Doctors advised against invasive ventilation on the basis that the infant's condition was terminal and it was not in the best interests of the infant to use a mechanical ventilator due to the risks of pain and distress associated with the procedure. The court ruled that such ventilation would cause pain and discomfort, would provide only temporary benefit and would not alleviate his underlying condition. Accordingly, the court accepted that the best interests were to receive pain relief and palliative care and did not grant the order applied for. Notably, however, the judge agreed with the applicant's contention that evidence relating to Mohammed's 'quality of life' was too value-laden to bear legal meaning and should be rejected. Subsequently, Mohammed was given non-invasive ventilation and was discharged from the hospital but succumbed to his condition after some months.

More recent case examples in Australia, as reviewed by Willmott et al. suggest a trend of an increasing number of cases being presented to the court.[15] Typically, where there has been conflict between the next of kin and the medical team, the judgements are based on the child's chance of survival. If survival was thought to be low or negligible, the court decided on withholding treatment. Even in the presence of underlying significant comorbidities, the decisions took into account the overall probability of improvement and the child's best interests.

Ethical Frameworks for Withdrawal or Limitation of Therapy

Transitioning to End-of-Life Care

Once a decision is reached to transition to end-of-life care, there are many components that must be considered to achieve this successfully including:

- family support
- determining family priorities during the palliative phase: e.g. home versus hospital, feeding
- Culturally and spiritually specific practices
- Child’s wishes
- Clinical goals and symptom control
- Organ and tissue donation

Greater weight should also be given to the psychological support of staff involved in the care of palliative paediatric patients due to *the increased* risk of moral injury and psychological harm as a result of general social attitudes towards paediatric death.

Paediatric Organ Donation

As previously discussed in Chapter 115 , consideration of organ and tissue donation is a routine component of end-of-life care in intensive care and paediatric patients are no exception to this. As with adults, the gap between the need for organs for transplantation and organ donation continues to grow. Every opportunity should be taken to maximise organ donation opportunities in the paediatric ICU, utilising best practice guidelines for donation.

Organ donation in paediatrics occurs follows very similar processes to adults and these are outlined in state and national best practice guidelines for organ and tissue donation. Paediatric donation occurs via the same two pathways: after the determination of circulatory death or after the determination of neurological death. Some key differences that relate to paediatric donation are the relative rarity of donation, consent, age-related differences in physiology that impact donor management, size-relate differences in suitability assessment for donation and the conduct of apnoea testing. The preconditions for brain death testing and the tests required to determine brain death are identical. Similarly, the process for donation after cardiac death is identical to that practised in adults.

Epidemiology

Paediatric organ donation represents about 5% of all organ donors in Australia and New Zealand, 7% in the United States and 2% of donations in the United Kingdom. [16-18] This stems from different presentations and patterns of injury in paediatrics, leading to a significantly smaller number of potential donors, but also that there is a higher rate of non-referral and a lower consent rate as a result of social mores surrounding paediatric death.

By far, donation after brain death is the most common pathway to donation in paediatrics. Only 3%–5% of paediatric donations occur after the determination of cardiac death, [16] however this fraction is increasing.

Paediatric donors typically present to PICU following immersion/drowning injury, out-of-hospital cardiac arrest and trauma. Typically, PICUs in Australia and the United States will handle <10 donations per year, and thus is an infrequent occurrence compared to the absolute number of donations that occur in adult units. Whilst the percentage of organ donations out of all deaths in ICU is similar in adults and paediatrics, the low mortality rate in PICU contributes to low donor numbers. The majority of donors are in the 11–17-year age group whilst children under 2 years of age are least likely to be donors.

Medical Criteria for Donation

As with adult donation, size, weight and blood group compatibility are crucial factors in the acceptance of organs for transplant. Extra-renal organs are generally weight and height-dependent, as these organs are orthotopic, however, there are some exceptions: split liver grafts and single lung transplants. Kidneys are histocompatibility matched and size is less important, except in the donor infant setting where a weight of >10 to 20 kg or aged >1 to 5 years means that kidneys may be considered as an en bloc transplant procedure for one recipient due to low kidney nephron mass. Suitability for donation is also dependent on the cause of death where the same exclusion criteria apply as in the adult setting.

Some diseases such as malignancy, untreatable sepsis or an unknown cause of death may exclude the possibility of donation. Every case is assessed at the time of notification to the donation service where immediate exclusions can be identified, however, a detailed investigation of the history is carried out with the family if consent is provided to proceed to donation.

The demonstration of death determined by neurological criteria enables all organs and tissues to be retrieved for transplantation without compromising ischaemic injury to the organs. Where death is determined by circulatory criteria, some organs may be precluded for donation as poorer transplant outcomes may be evident in the face of warm ischaemic time between death, retrieval and organ perfusion. Whenever a child is anticipated to die and would be a potential donor of organs and/or tissues, discussions should be undertaken with their parents or guardian who should be given an opportunity to consider donation and authorise donation from their child.

Consent in Paediatrics

Most countries will have an organ donation registry in place, whether it is an ‘opt-in’ or an ‘opt-out’ system. Depending on the definition of the legal age to register on the local registry, for example older children may be able to register their intention for donation but may require their parent’s agreement at the time of registration. The applicability of any legal framework regarding donation may not apply to children and the decision-making defaulting to parents/guardian and their preferences.

Most children are not of the age to consider/express an opinion on organ donation let alone legally provide consent. In Australia, children from the age of 16, or those determined to have ‘Gillick’ competence* can consent to donation. Gillick competence is a concept born out of the UK trial ‘Gillick vs West Norfolk AHA’ (1986) and refers to the assessment and determination of capacity in children under the age of 16 that enables them to consent to treatment. [19] Due to the nature of organ donation, ultimately the senior available next of kin (SANOK), usually parents, are required to provide consent for organ donation to proceed. Obtaining consent for donation should follow best practice principles. In Australia, as in many other countries, best practice compromises a collaborative model utilising specially trained donation requestors working with the treating team to ensure the family has the best opportunity for informed consent. To date, there is a paucity of programmes that provide training specialised in the paediatric area.

Inflicted Injury and Organ Donation

Inflicted injury and death due to trauma both necessitate obtaining coronial consent prior to proceeding with donation. In some Australian states, coronial consent for paediatric cases is obtained prior to approaching the SANOK for consent. This process also allows the organ donation team to organise necessary investigations to support coronial investigations and may facilitate donation occurring. As coronial involvement is very common in the types of patients who meet the criteria for referral for consideration of organ donation, support from coronial services is essential in a successful organ donation programme. In the United States, this is evidenced by a statement from the National Association of Medical Examiners that states 'Medical examiners and coroners should permit the recovery of all organ and/or tissue from decedents falling under their jurisdiction in virtually all cases, to include cases of suspected child abuse, other homicides and sudden unexpected deaths in infants'. Similarly, in Australia, Donate Life, and in the United Kingdom, the NHS Organ Donation work closely with coronial services to ensure the wishes of the next of kin for their child to be a donor are respected as much as practical.

Age-Related Physiological Differences

Age-related physiological differences between neonates, infants and children necessitate differences in the management of the potential donor compared to adults.

Whilst the physiological perturbations that follow brain death are similar, the physiological targets for the cardiovascular support of the potential organ donor post-brain death are determined by the age-related normal values.

Medications used, whilst identical to adults, need to be dosed based on age, weight or body surface area of the donor. Recommendations regarding medications and their dosing can be found in the relevant state or national guidelines on the management of paediatric organ donors.

Determination of Brain Death: Apnoea Testing

Criteria and preconditions for the determination of death, both neurological and circulatory are identical to that used in adults. The exception to this is neonates (see later). The devices used to provide oxygenation during the apnoea test need to accommodate the differences in respiratory physiology to ensure the test is valid.

Whilst the same devices:

- An insufflation cannula in the endotracheal tube (ETT)
- A t-piece circuit attached to the ETT
- Or a self-inflating bag system such as a Mapleson circuit ± a PEEP valve

Can be used to insufflate oxygen during the apnoea test, care must be taken to ensure the flow rate used does not lead to washout of alveolar CO_2. Due to the smaller lung volumes and minute ventilation of infants and small children, high flow rates of apnoeic oxygenation devices washout CO_2 in the alveolus preventing its accumulation and thus failing to adequately stimulate the respiratory centre for the test to be valid.

Clinical studies have recommended the use of flow rates of 1 L/min/year of life up to 12 L/min. Additionally, children are more prone to desaturation during the apnoea test due to their higher metabolic rates and lower functional residual capacity. A recent publication has suggested the use of a self-inflating bag with a PEEP valve is superior in minimising the risk of desaturation during the apnoea test. [20]

In smaller children and infants, care must be taken to ensure that an insufflating cannula does not prevent the excursion/release of alveolar gas via the lumen of the endotracheal tube as this may result in barotrauma to the lungs.

High-flow oscillatory ventilation (HFOV), a ventilation mode used almost exclusively in paediatric and neonatal intensive care, can also be used to facilitate apnoea testing. Once the patient has stabilised on HFOV, the oscillations could be discontinued but mean airway pressure maintained to facilitate accumulation of CO_2.[21]

Neonates

Eligibility for donation in neonates has a lower size limit and also depends on the size of the potential recipients. Typically, a child is required to be >5 kg in weight to be considered a potential tissue or organ donor. This, combined with some of the challenges surrounding the diagnosis of brain death in neonates, means that neonatal donation is a rare occurrence. In Australia and the United Kingdom, examination for brain death and subsequent donation can only occur in children >37 weeks of age or older.

In addition to the clear physiological differences in neonates, drug doses and pharmacokinetics, there are also differences in brainstem reflexes that necessitate variations from the criteria for brain death assessments made in older children and adults. In neonates and ex-premature neonates less well-developed respiratory and other brainstem reflexes may cloud the interpretation of the clinical testing, such as the observation that neonates may have inadequate stimulation of their respiratory centre in the presence of 100% oxygen. Consequently, many countries require neonates to be of a minimum gestational age and mandate a longer period of observation before clinical testing can occur.

In jurisdictions like Australia for example, declaration of death by neurological criteria clinically and subsequent donation can only occur in children >37 weeks of age and older. In addition to a minimum age criterion, there is often a period of observation that must occur before testing can be conducted. Internationally there is some variation in the required observation period that must occur prior to assessment for death by neurological criteria, however, in neonates, it is generally longer than that required in older children and adults. In the United Kingdom and the United States, a period of 24 hours of observation must occur prior to any clinical testing for brain death. Similarly, in Australia term neonates under 30 days old must be observed for 24 hours and have a further 24 hours window between the first and second clinical examination. In premature neonates, clinical testing when combined with brain perfusion scans can be used to diagnose death by neurological criteria. In the United States, the period between examinations is 24 hours for neonates and 12 hours for children born at term and >30 days of age.

Utility of imaging in this age group is also limited and poorly studied but generally thought to be less sensitive. The presence of open fontanelles in neonates and infants makes most ancillary testing less reliable. Another challenge in ancillary studies is that some of these children may have cerebral blood flows that exist below the detectable limits for some of the technologies invalidating those technologies as potential ancillary studies. In the United States, both MRI and CT are not considered to be ancillary studies and cannot be used to determine neurological death. Brain perfusion is generally accepted as an ancillary study for the determination of neurological death where preconditions for examination cannot be met even in preterm neonates.

Ancillary Testing

In the United States, United Kingdom and Australia, ancillary testing is used as an adjunct for the diagnosis of brain death where clinical criteria cannot be met, however, it is not mandatory. Up to 38% of European countries, however, required mandatory imaging as part of determination of neurological death.

As in adults, four-vessel angiography is the gold standard for determining the absence of cerebral blood flow. It is technically difficult to perform in infants and not readily available in many paediatric centres precluding its use. Similarly to adults, transport to angiography suites is associated with risks of transportation and the management of the physiologically unstable patient in a location removed from the PICU.

Radionuclide studies are the most widely used ancillary tests used to diagnose brain death in paediatric patients. In the original American Academy of Paediatrics (AAP) 1987 guidelines EEG was a precondition for paediatric brain death examination, however, this requirement has been removed in the 2011 revision due to its poor sensitivity. AAP guidelines recommend where the ancillary testing demonstrates flow, regardless of the clinical examination findings, the child cannot be declared brain dead. The recommended interval for repeating tests is 24 hours to allow adequate clearance of Tc-99m.

Determination of Death by Circulatory Criteria

The criteria for determining death by circulatory criteria do not differ between adults and children.

Paediatric Tissue Donation

In all situations where end-of-life care is being considered, the potential for tissue donation should be explored when organ donation has been excluded due to medical suitability, size or blood group incompatibility. Tissue donation in children may be precluded due to age, size and weight, cause of death or medical conditions. By nature, tissue donation is more restrictive in their exclusion criteria as tissue is regulated in Australia under the Therapeutic Goods Administration legislation, the Food and Drug Administration (through title 21 code of federal regulations pts 1270 and 1271) and by the Human Tissue Regulation (2007) in the United Kingdom. Absolute contraindications to donate tissue include: haematologic and metastatic malignancy, transmissible disease and untreated sepsis. In rare instances, eye tissue donation may be considered for malignancy and sepsis.

General Age and Weight Criteria

Whilst the age/weight threshold for tissue donation continues to change with new evidence and technological advancements, in most paediatric cases, only corneas and cardiovascular tissue will be suitable for donation. Skin and musculoskeletal tissue are weight, age and height dependent. As a rule of thumb, eye tissue donation would be considered in children >2 years of age, cardiovascular tissue usually will be on a case-by-case basis with a loose cut-off of 5 kg, skin tissue is considered for children who weigh >60 kg and musculoskeletal tissue is generally possible in children >16 years old.

Consent for tissue donations

The family donation conversation for tissue donation follows the same pathway and best practice guidelines as organ donation in the ICU. The treating clinical team retains leadership for family communications about the patient's prognosis. It is the responsibility of the treating clinical team to ensure that the family understands that death is expected to occur following the withdrawal of cardiorespiratory support (both ventilated or non-ventilated patient), before they are asked to consider donation. It is important that the family are told that tissue retrieval may occur several hours after the death and will not interfere with the time that they wish to spend with their child. However, tissue retrieval must take place within 24 hours of circulatory death.

Paediatric poisoning and envenomation

Sainath Raman, Angela Burgett and Carol J. Wylie

Epidemiology

Poisoning in childhood is common. Over 10-year period (2009–2019) 33,400 children under 15 years of age were admitted to hospitals for pharmaceutical or nonpharmaceutical exposures or envenomation. [1] In Australasia, this is approximately 78.4/100,000 per year. 56% of these children were under the age of 5 years. Adolescents (15–17 years) have the highest rate of hospitalisation at 600/100,000 population (2012–2013). [2] A minority were life-threatening, but no deaths occurred, and hospitalisation was required on average for 2 days. Poisoning often occurs in the home when a single prescribed or over-the-counter medication or a household product is ingested. Whatever intervention is used to manage poisoning, care should be taken to ensure that it does not cause additional harm. [3]

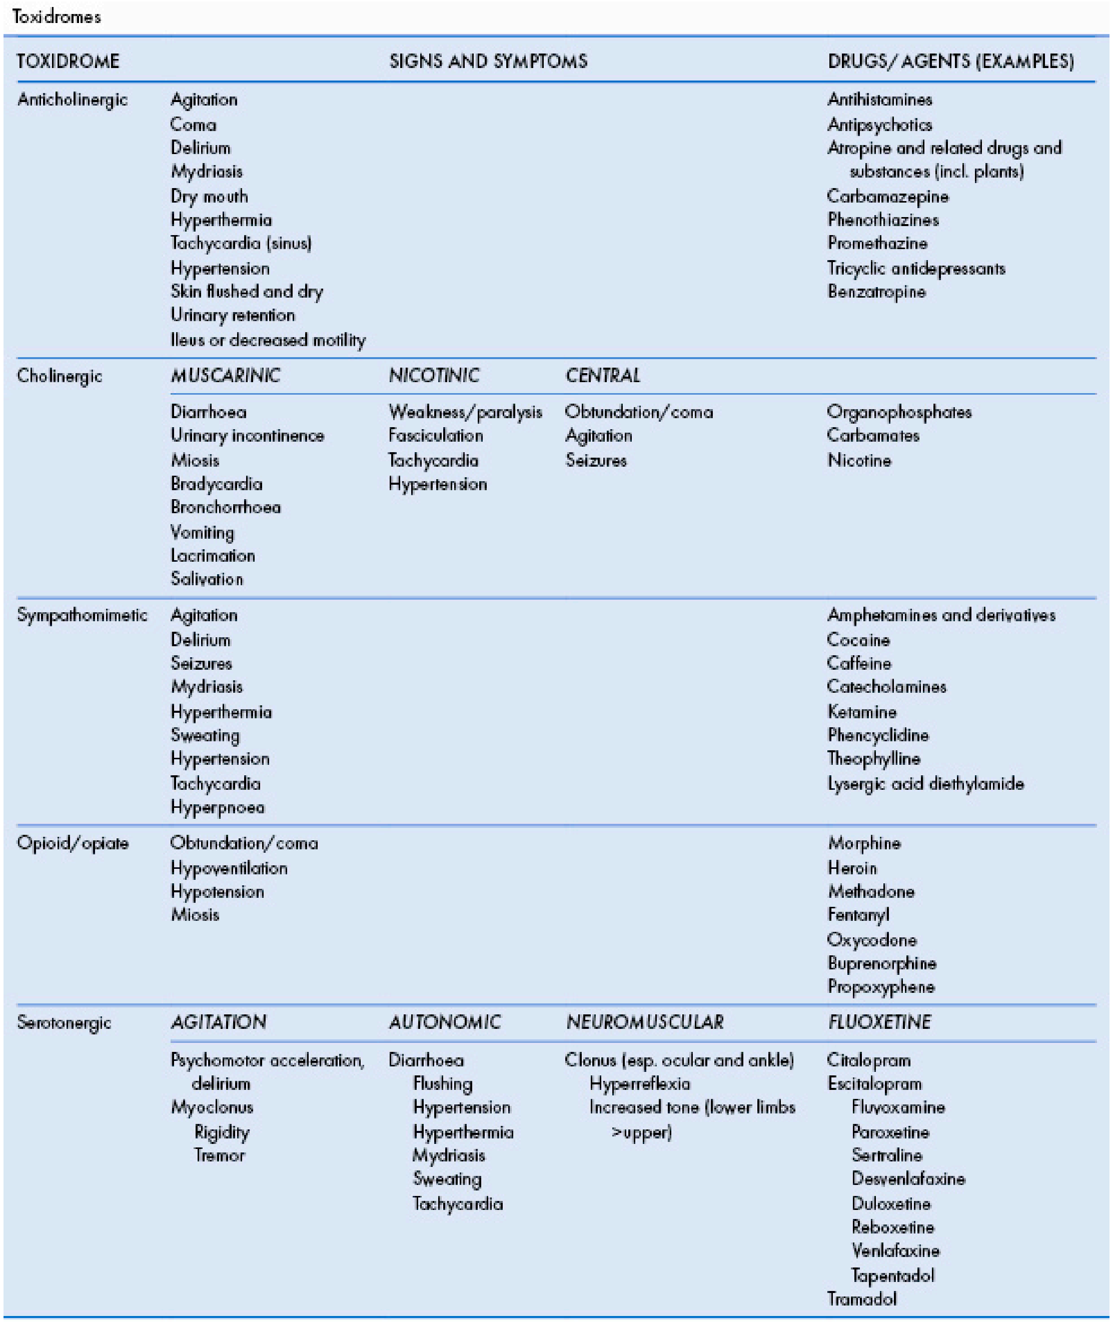
Poisoning among young children is called ‘accidental’ usually due to the result of inadequate supervision or unsafe storage of poisons. Occasionally, poisoning in childhood is either truly accidental as in ingestion of a decanted chemical or is part of a syndrome of child abuse, or is iatrogenic as when a parent mistakes medications at home or when medical or nursing staff make errors in drug administration in hospital. [4]

Self-poisoning in late childhood (10–14 years) or adolescence is usually with the intention to manipulate their psychosocial environment or to commit suicide or is the result of substance abuse. Girls more commonly had self-inflicted poisonings with pharmaceutical drugs with boys more likely to suffer drug and alcohol abuse. [5] It is important to consider deliberate poisoning in this age group, especially around prescribed or over-the-counter medicines for the child or within the household, for example, paracetamol, especially in children where the symptoms and clinical picture do not fit the history. All such circumstances of poisoning require remedial action.

Commonly, the diagnosis of poisoning in paediatric practice is self-evident from a history detailed by parents or guardians. Although a single poison is usually involved, the possibility of several or multiple poisons should be considered. Occasionally, the diagnosis is unknown on presentation. Any child who presents with unexplained obtundation, seizures, hypoventilation, hypotension or has a metabolic derangement must have poisoning excluded.

Recognition of a ‘toxidrome’, a constellation of symptoms and signs, may make the diagnosis. [6–8] Although numerous toxidromes exist, the five prominent types and their causative drugs or agents are shown in Table 99.1 .

Table 99.1



Toxidromes

TOXIDROME	SIGNS AND SYMPTOMS			DRUGS/AGENTS (EXAMPLES)
Anticholinergic	Agitation Coma Delirium Mydriasis Dry mouth Hyperthermia Tachycardia (sinus) Hypertension Skin flushed and dry Urinary retention Ileus or decreased motility			Antihistamines Antipsychotics Atropine and related drugs and substances (incl. plants) Carbamazepine Phenothiazines Promethazine Tricyclic antidepressants Benzatropine
Cholinergic	*MUSCARINIC*	*NICOTINIC*	*CENTRAL*	
	Diarrhoea Urinary incontinence Miosis Bradycardia Bronchorrhoea Vomiting Lacrimation Salivation	Weakness/paralysis Fasciculation Tachycardia Hypertension	Obtundation/coma Agitation Seizures	Organophosphates Carbamates Nicotine
Sympathomimetic	Agitation Delirium Seizures Mydriasis Hyperthermia Sweating Hypertension Tachycardia Hyperpnoea			Amphetamines and derivatives Cocaine Caffeine Catecholamines Ketamine Phencyclidine Theophylline Lysergic acid diethylamide
Opioid/opiate	Obtundation/coma Hypoventilation Hypotension Miosis			Morphine Heroin Methadone Fentanyl Oxycodone Buprenorphine Propoxyphene

Individual poisons may require specific measures. Consult current toxicology texts and guidelines [6–8] or contact a local poisons information centre for advice. Refer also to Chapter 90 . Working knowledge of important poisons is indispensable for paediatric practice. Several poisons or classes of poison are potentially fatal to a small child if taken as a single tablet or a teaspoonful. [9] These include opiates (oxycodone, methadone and buprenorphine), quinine derivatives, cyclic antidepressants, sulfonylureas, calcium channel blockers, colchicine, button batteries, essential oils and some pesticides. If a poison is unfamiliar, a poison information centre can provide valuable information to assist with the management of the poison; however, clinical judgement will remain with the treating physician.

Principles of Management

A standardised risk assessment-based method allows for a sensible structured approach to all poisonings regardless of agent.

The eight basic principles of the risk assessment-based approach are: resuscitation, risk assessment, supportive management, investigations, decontamination, enhanced elimination, antidotes and disposition (RRSI DEAD).

Resuscitation

Airway/breathing/circulation, in addition, seek and treat hypoglycaemia, seizures and hypo/hyperthermia. The resuscitation of a child is detailed in Chapter 100 of this volume. When conventional resuscitation is failing, extracorporeal life support may be required.

Risk Assessment

Risk assessment should occur as early as possible in the poisoned child. This gathers important information about the child, the suspected agent, the intent of the poisoning and the time of ingestion/exposure. It is important to base the risk assessment on the 'worst case' scenario if a full history of the agent or agents and total dose are unable to be obtained. [10]

There should be a detailed history of the patient, including age, weight, medical history, medications and allergies. The agent or agents must be documented, including the intrinsic toxicity, the route of exposure, whether it was an acute or chronic exposure, approximate time of exposure and the intent. The current patient symptoms should be correlated with the agent, dose and time since exposure, and if it does not, a review of the risk assessment should be undertaken. If the agent is unknown the clinician should consider the agents potentially available to the child. [11]

The aim of the risk assessment is to allow early recognition of trivial poisonings so reassurance may be provided to parents and caregivers, avoiding unnecessary investigations and interventions. Equally, it may identify potentially significant ingestion or envenomation and tailor an appropriate plan for management with early identification of a possible antidote and facilitate appropriate disposition planning. [10, 11]

Supportive Care and Monitoring

Once resuscitation and risk assessment have been addressed supportive care and planning further disposition can occur. Acute poisoning may affect cardiovascular, respiratory and central nervous systems resulting in considerable risk of morbidity and mortality. Close monitoring of these systems in an appropriate setting such as an emergency department or intensive or high-care setting ensures that the trajectory of the patient follows that of the expected risk assessment. [10] The duration and requirements of a child's observation are based on the agent or exposure, formulations, for example sustained-release preparations and predicted complications.

Investigations

Investigations in acute poisoning are generally considered to be screening tests or specific tests. Screening tests are those considered in all poisonings that may aid in identifying occult ingestions where there is directed and specific treatment. These investigations include a 12-lead ECG, a bedside blood glucose and a paracetamol level. [10] In children where the ingestion is a true accident and a clear history of exposure, timing and agent exists, such screening tests may be negated.

The ECG is a non-invasive test that can identify occult and potentially harmful arrhythmias. A bedside glucose testing can identify hypoglycaemia that may be otherwise missed in a patient with an altered mental status in a toxic ingestion or exposure. Finally, a paracetamol level can identify a potential and unreported overdose that may be occult in the early stages. The prevention of significant morbidity secondary to paracetamol overdose can be prevented by early administration of acetylcysteine. [12, 13]

More specific investigations are going to be determined by the suspected toxic ingestion or exposure based on the risk assessment. Specific tests may include specific drug levels such as salicylates, lithium or anticonvulsant levels and may guide management. Further tests should only be ordered if their outcome is considered to assist in the management or risk assessment of the child. [12] Potential indications for other tests may aid in a differential diagnosis, establish an indication for antidote administration, establish an indication for an elimination therapy and or monitor a response to a therapeutic intervention.

Decontamination

Decontamination in paediatric poisoning can be considered where the risk assessment suggests there will be a significant benefit. It is important to note that most childhood poisonings recover with merely supportive care or no treatment at all. [14]

Simple decontamination techniques for skin exposure, such as removing clothing and bathing the patient with soapy water, may decrease the skin absorption and potential risk to clinicians treating children who have been exposed to hazardous chemicals. [10, 11, 14]

Irrigation of eyes with isotonic (0.9% sodium chloride) saline will provide benefits when children have chemical exposure to the eye. This generally requires significant volumes of fluid and based on the age of the child, level of distress and compliance, it may prove difficult without a level of sedation and therefore needs to be considered on risk and a case-by-case basis. [11]

Since most of the poisoning in childhood is by ingestion, potential exists for removal from the gastrointestinal tract before absorption. Many of the gastrointestinal decontamination techniques are associated with potential adverse effects and have not been demonstrated to have significant benefits. Choices such as gastric lavage and induced emesis are no longer recommended. Whole bowel irrigation is not routinely administered again due to the risk-benefit analysis. There may be some benefit in individual cases when sustained-release or enteric-coated medications are taken in large quantities. [11, 14]

Activated Charcoal

Charcoal adsorbs many drugs but, while limited, there is still evolving evidence for its efficacy, particularly in paediatrics. The use of activated charcoal in the paediatric population has a limited role and the decision to use it should be made in consultation with a clinical toxicologist and based on the time since ingestion and whether the toxin/drug is considered to still be in the upper gastrointestinal tract and whether the drug will be effectively bound to activated charcoal. Most drugs and toxins are bound by activated charcoal, however, agents such as hydrocarbons, alcohols, metals, including lithium, potassium, iron and lead and all acids and alkali agents are not bound, so activated charcoal should not be used in poisonings from these agents.

Activated charcoal is not pleasant to drink and is associated with vomiting in poisoned children. [11–16] It can be mixed with ice cream and/or toppings to make it most palatable. [15]

Children must be alert to be considered for activated charcoal due to the significant risk of pulmonary aspiration which is associated with marked morbidity and mortality. Where the risk assessment suggests a significant poisoning and activated charcoal is indicated, and there are concerns for a reduced, or potential reduced level of consciousness, a nasogastric tube may be placed and should be confirmed via x-ray.[11–16]

Activated charcoal should be administered within 2 hours of ingestion. The dose is 1 g/kg up to 50 grams. In severe poisonings, charcoal may be considered more than 2 hours after the time of ingestion and in the event of ingested modified release preparations, charcoal can be considered up to 4 hours after ingestion. Where it is unclear of the benefit of activated charcoal, consult a poison information centre or a clinical toxicologist.[11,12]

Complications

Aspiration of charcoal causes severe and often fatal pneumonitis, bronchiolitis obliterans and acute respiratory distress syndrome. Inadvertent intratracheal instillation of activated charcoal causes a significant increase in lung microvascular permeability and arterial blood gas derangements.[12,17]

Constipation is common after charcoal, but bowel obstruction is fortunately rare. The addition of a laxative (e.g. sorbitol or magnesium sulphate) is not recommended because, although transit time through the gut is decreased, efficacy of the charcoal is reduced and life-threatening fluid and electrolyte imbalance may occur.[18]

Enhanced Elimination

Enhanced elimination techniques are used to increase the removal of the toxin from the body. Common techniques utilised include multidose-activated charcoal, extracorporeal elimination and urinary alkalinisation.

Multidose-Activated Charcoal

Multidose-activated charcoal works via increasing drug clearance by disrupting enterohepatic circulation or gastrointestinal dialysis. The patient must be cooperative or be intubated. Although multiple reports exist in experimental and clinical practice,[10,11,14] evidence is building to show that this therapy reduces mortality and morbidity. Only in life-threatening poisoning by carbamazepine, dapsone, slow-release paracetamol, calcium channel blockers, colchicine, warfarin, phenobarbital, quinine or theophylline should multiple-dose activated charcoal be considered.[11,14]

Extracorporeal Decontamination

Occasionally, removal from the circulation by an extracorporeal technique is needed by haemodialysis, haemofiltration or plasmapheresis. Examples of toxins removable by haemodialysis and haemofiltration include lithium, metformin, toxic alcohols, theophylline, salicylates, carbamazepine and valproic acid. Examples of toxins removed via plasmapheresis include phalloid mushroom intoxication, tricyclic antidepressants, thyroxine, verapamil, diltiazem and carbamazepine.[18,19] Such techniques, combined with extracorporeal circulatory support, may be considered when conventional therapy is failing or is anticipated to fail, but expert clinical toxicology opinion is recommended.

Alkaline Diuresis

Urinary alkalinisation has a limited role in paediatrics but may be considered for exposures to aspirin and other salicylates, barbiturates and chlorophenoxy herbicides, by reducing the reabsorption of these agents in the distal renal tubules. Sodium bicarbonate is given intravenously at 1 mmol/kg followed by an infusion of 25 mmol/hour in intravenous fluid titrated to maintain alkaline urinary pH between 7.5 and 8.0 without exceeding serum pH of 7.5. Monitor serum pH, sodium, potassium and calcium and avoid clinical problems of fluid overload.[11–14]

Antidotes

An antidote counteracts the clinical effects of a toxin or chemical. Most antidotes are not 100% effective with morbidity and mortality still occurring despite their use. The use of antidotes should be considered when there is evidence of benefit over risk to their use. There are only a few antidotes that are beneficial and used in routine clinical practice. It is important to be aware of clinical toxidromes and understand the use of the antidotes that may be indicated for each.

Naloxone

Naloxone is an opioid receptor antagonist. It can be given intranasally, intramuscularly or intravenously. It is indicated in those children who have had an accidental or intentional opiate overdose with a respiratory rate of less than 12 breaths per minute. The dose is 0.01 mg/kg intravenously up to 0.2 mg in incremental doses every 3–5 minutes until the respiratory rate is at the desired rate. The maximum dose is 10 mg.[11,20] If intravenous access is unable to be established, an intramuscular dose of 0.4–2 mg or an intranasal dose of 1.8 mg or one spray from a 1.8 mg/0.1 mL preparation.[11]

Acetylcysteine

Acetylcysteine is used in intentional or accidental paracetamol overdose when indicated by the risk assessment. Most countries have very clear guidelines available for its use. The mechanism is to maintain or replenish glutathione reserves in the liver and enhance the non-toxic metabolism of paracetamol. It lessens liver toxicity in paracetamol overdose if given in the first 8 hours. [11, 13]

Disposition

Paediatric patients exposed to toxic substances or envenomation need to be admitted to a unit that is appropriate to provide suitable monitoring and supportive care, with access to an intensive care unit if required. Early risk assessment is pre-hospitable, usually by a poison’s information service may enable monitoring and observation at home or guide the observation requirements if hospital observation is advised.

Regular observation of the paediatric population may be carried out initially in an emergency department or short-stay units, with occasional extended observation required in a paediatric ward or high-dependency setting. [10, 14]

Poisoning by Specific Substances

Like adults, children are poisoned regularly by therapeutic prescription or over-the-counter therapeutic drugs and substances (see Chapter 101). The range of poisons reflects their availability in the home. In surveys, the most common agents responsible for hospital admission of children are benzodiazepines, anticonvulsants, paracetamol, antidepressants, antipsychotics and cardiovascular drugs. [20] Fatal poisonings are often by opiates, especially methadone and pesticides. [20, 21]

The inquisitive nature of young children results in poisoning by substances not normally regarded as dangerous and not as commonly encountered in adults. A few of these are considered here briefly.

Opioids

Opioids account for two-thirds of deaths due to drug poisoning in children. [21] A single ingestion of an opioid tablet or a mouthful of liquid can be potentially fatal. Opioids cause significant hypoventilation that is disproportionate to the level of sedation together with pinpoint pupils. Methadone and oxycodone can be associated with prolonged QT. [22]

Management of opioid overdose requires attention to the resuscitative measures surrounding the airway, breathing and circulation. In some cases, oral activated charcoal can be considered in overdoses of sustained-release opioids if the patient presents early. [11] Definitive treatment of the sedation and respiratory depression will be by titrated doses of naloxone 0.4–2.0 mg intramuscularly. [11] Alternatively, a child may be given a 10 microgram/kg IV dose (up to 200 µg), repeated every minute to an increased level of consciousness and oxygen saturations of greater than 92% in room air. If the child becomes sedated after initial recovery the total initial naloxone dose can be readministered and a naloxone infusion can be considered at 2/3 of the total initial bolus dose, given in an hour. [10]

A child who presents with a suspected opioid overdose should have a minimum observation period of 4 hours for standard preparations (12 hours if no naloxone administered) and up to 12 hours for controlled release preparations (24 hours if no naloxone administered) before discharge from the emergency department. Discharge at night should be a rare occurrence. [14]

Button Batteries

Ingestion may cause electrolytic injury and potentially corrosive, toxic or pressure injury. There are many types of batteries that contain a variety of substances; the most important is lithium.

Identifying a potential button battery ingestion is difficult and symptoms may mimic gastrointestinal or respiratory illnesses. A high index of suspicion is required, especially in the paediatric population under the age of 5 years, where the story is atypical, and ingestion may have been unwitnessed, and the child is unable to give a reliable history. [11] An x-ray should be immediately ordered to identify a lodged button battery in the oesophagus, chest or abdomen. Impaction in the oesophagus is the most significant situation; this can result in oesophageal perforation and tracheo-oesophageal fistula or aorto-oesophageal fistula. An impacted battery must be removed endoscopically as soon as possible. Lithium batteries are large and impact readily and they have higher voltages than other types. [23] Electrolysis commences as soon as the battery surfaces are immersed in oesophageal fluid. The consequence is local and surrounding tissue destruction, including the trachea. Strong alkali is produced at the cathode and strong acid is produced at the anode. Sufficient follow-up is necessary to detect early any oesophageal and tracheal damage and to ensure that a battery in the stomach or distal bowel is eliminated. [23–25]

Essential Oils

The oils from certain plants contain mixtures of terpenes, alcohols, aldehydes, ketones and esters, which are used domestically for various purposes. The well-known oils are eucalyptus, turpentine, citronella, cloves, tea tree, peppermint, wintergreen and lavender. Toxicity can vary depending on the type of oil and the volume ingested. In general, small amounts cause depression of the conscious state, irritation of the gastrointestinal tract, liver dysfunction and pneumonitis if inhaled. For example as little as 5 mL of eucalyptus oil [26] or 15 mL of turpentine may cause depression in the conscious state.

Emesis should not be induced. Activated charcoal is not indicated due to rapid gastrointestinal absorption. Acetylcysteine may be considered in children where hepatotoxicity secondary to clove or pennyroyal oil has occurred. [11]

Paracetamol

This is the most common drug ingested by children in an accidental, iatrogenic or deliberate overdose situation. Overdose has the potential for hepatic failure and, less commonly, renal failure. The onset of hepatic toxicity may be delayed; however, alanine transaminase changes are usually apparent after 24 hours. The hepatic toxicity in part is caused by the metabolite of the drug (*N*-acetyl-*p*-benzoquinoneimine), which accumulates when endogenous glutathione, which facilitates the conversion of *N*-acetyl-*p*-benzoquinoneimine to non-toxic substances, becomes exhausted. An adequate supply of glutathione is ensured by the administration of acetylcysteine (NAC), a glutathione precursor that can be administered intravenously (see Table 99.2).

Table 99.2

Antidotes to some poisons

POISON	ANTIDOTES	COMMENTS
Amphetamines	Diazepam 0.05–0.1 mg/kg IV over 2–5 mins every 10 mins Midazolam 0.05–0.1 mg/kg IV or IM every 3–4 minutes to decrease agitation and tachycardia Droperidol: 0.1–0.2 mg/kg up to 10 mg intramuscularly; repeat once after 15 minutes if required. Maximum dose: 0.4 mg/kg up to 20 mg per event	Treatment for tachyarrhythmia, agitation and hypertension
	Glyceryl trinitrate 0.5–5 micrograms/kg/min IV infusion- Titrate to effect	Treatment for hypertension
Anticholinergic toxidrome (antimuscarinic)	Physostigmine 0.01 mg/kg up to 0.5 mg IV can be repeated to treat recurrence of delirium due to the short half-life of physostigmine	Treatment of anticholinergic delirium Beware cholinergic effects including bradycardia, bronchospasm and weakness
Aspirin and salicylates	Sodium Bicarbonate 8.4% 1 mmol/kg (up to 100 mmol) IV as an initial dose followed by 0.5mmol/kg/hr (up to	To alkalinise the urine to enhance elimination of aspirin and other salicylates. Aim for urinary pH of 7.5 to 8.0, serum pH

POISON	ANTIDOTES	COMMENTS
	25 mmol/hr) by intravenous infusion	to not exceed 7.5
Benzodiazepines	Flumazenil IV at 0.01 mg/kg increments to clinical effect up to 1 mg	Specific receptor antagonist. Beware convulsions
Beta blockers	Atropine 0.02 mg/kg up to 0.6 mg IV repeat once after 15 min if required for bradycardia Adrenaline 0.1 micrograms/kg IV every 2–3 min aiming for adequate perfusion, followed by infusion 0.02–0.2 micrograms/kg/min. High-dose insulin euglycaemia (HIET) therapy, if response to adrenaline is inadequate. Short-acting insulin 1 unit/kg IV by slow injection with glucose 10% 2.5 mL/kg IV by slow injection. Followed by IV infusion: short-acting insulin 1 unit/kg/hr (titrated up to 10 units/kg/hr with glucose 10%, 2.5 mL/kg/hr up to 100 mL/hr). 50% dextrose infusion can be used if central venous access is available.	High-dose inulin euglycaemia therapy (HIET): monitor blood glucose and serum potassium. Consult with clinical toxicologist for advice re: HIET

POISON	ANTIDOTES	COMMENTS
	Isoprenaline 0.1 micrograms/kg IV every 2–3 minutes according to heart rate response, followed by infusion 0.01–0.05 micrograms/kg/min	
Calcium channel blocker	Calcium chloride IV 10%, 0.14 mmol/kg up to 6.8 mmol (0.2 mL/kg up to 10 mL) OR Calcium gluconate IV 0.13 mmol/kg up to 6.6 mmol (0.6 mL/kg up to 30 mL) Repeat after 10 minutes if required, followed by an infusion to maintain serum ionised calcium between 1.5 to 2.0 mmol/L Calcium chloride infusion: 0.02 mmol/kg/hr. Occasionally, additional inotrope or vasopressor support may be required.	Antagonises at receptors
Carbon monoxide	Oxygen 100% 15 L/min for minimum of 6 hours	Decreases carboxyhaemoglobin
Cyanide	For mild cyanide poisoning: Hydroxycobalamin (Vit B_{12}) 70 mg/kg IV up to 5 g diluted in sodium chloride 0.9 % over 15 minutes	‘Cyanide antidote kit’ provides hydroxycobalamin at the high strength required. Nitrites form methaemoglobin-

POISON	ANTIDOTES	COMMENTS
	OR Sodium thiosulphate 25% IV 1.6 mL/kg up to 50 mL (400 mg/kg up to 12.5 grams) over 10 minutes. For moderate-to-severe poisoning, use both hydroxycobalamin AND sodium thiosulphate, at above doses. If hydroxycobalamin is unavailable: Sodium nitrite 3% IV 0.13–0.33 mL/kg up to 10 mL (4–10 mg/kg up to 300 mg) over 5 minutes then sodium thiosulphate as above	cyanide complex: beware of excess methaemoglobin—restrict to <20%. Note: In cases of smoke inhalation, there may be both cyanide and carbon monoxide poisoning. Do not use sodium nitrate in these cases, use sodium thiosulphate alone
Digoxin	Atropine 0.02 mg/kg up to 0.6 mg IV, repeat as required	Use for bradycardia while accessing digoxin immune Fab
	Digoxin immune Fab 80 mg (2 vials) IV over 30 minutes If patient is in cardiac arrest, use 200 mg (5 vials) IV as a rapid injection	Binds digoxin
Heparin unfractionated	Protamine 1 mg per 100 units unfractionated heparin, maximum rate 5 mg/minute (max 50 mg)	Direct neutralisation Risk of hypotension, flushing, pulmonary oedema and bradycardia

POISON	ANTIDOTES	COMMENTS
Hydrofluoric acid	Calcium chloride IV 10%, 0.14 mmol/kg up to 6.8 mmol (0.2 mL/kg up to 10 mL) OR Calcium gluconate IV 0.13 mmol/kg up to 6.6 mmol (0.6 mL/kg up to 30 mL) Repeat after 10 minutes if required Calcium gluconate gel 2.5% topically to exposure site	Parenteral calcium indicated for systemic toxicity If calcium gluconate gel is not available, it can be made using calcium gluconate 931 mg/10 mL mixed with 30 g water soluble gel
Iron	Desferrioxamine 15 mg/kg/hr until iron concentration falls below 60 micromol/L Indicated if level >90 micromol/L or severe systemic toxicity	Hypotension is common, ensure adequate hydration before infusion. Beware anaphylaxis
Isoniazid	Pyridoxine (vitamin B_6) at a dose equivalent to dose of isoniazid ingested, up to 5 g IV at a rate of 500 mg/minute. If dose of isoniazid unknown give 70 mg/kg (max 5 g) IV at a rate of 500 mg/minute. If intravenous pyridoxine is not available in adequate doses, or seizures persistent give benzodiazepines	Metabolic acidosis may be mildly exacerbated

POISON	ANTIDOTES	COMMENTS
Lead	Succimer (dimercaptosuccinic acid-DMSA) 10 mg/kg (up to 600 mg) every 8 hours orally for 5 days, then every 12 hours for 14 days Dimercaptopropane-1-sulphonate (DMPS) 5 mg/kg intravenously every 6 hours for 5 days OR As combination therapy with Dimercaprol (BAL) 3 mg/kg intramuscularly every 4 hours for 2 days, then reduce to 3 mg/kg every 12 hours for a further 5–7 days	Chelating agents Oral chelation is preferred, but urgent parenteral chelation therapy is indicated in patients with symptoms of lead encephalopathy
Local anaesthetic drug cardiovascular toxicity	Lipid emulsion 20% IV 1.5 mL/kg over 1 min, then infusion 0.25–0.50 mL/kg/min as needed to restore haemodynamic stability	Evidence for use is limited to bupivacaine-induced cardiovascular collapse if standard resuscitation and supportive care measures are insufficient. Can be considered in cases of other local anaesthetic toxicity
Methaemaglobinaemia (potential causes: nitrites and nitrates, dapsone,	Methylene blue IV 1–2 mg/kg over several minutes	Reduces methaemoglobin to haemoglobin.

POISON	ANTIDOTES	COMMENTS
naphthalene, some antimalarials and some pesticides/herbicides)		Note: methylene blue can interact with serotonergic drugs resulting in serotonergic toxicity
Methanol, ethylene glycol, glycol ethers	Fomepizole (4-methylpyrazole) 15 mg/kg IV over 30 min, then 10 mg/kg every 12 hours for first 48 hours, then 15 mg/kg every 12 hours	Inhibits alcohol dehydrogenase
	Ethanol 10% IV loading dose 6 mL/kg diluted in glucose 5%, then 1 to 2 mL/kg/hr up to 100 mL/hr to maintain blood level 0.1%–0.2% (100–200 mg/dL)	Competes with poison for alcohol dehydrogenase
Methotrexate	Leucovorin (folinic acid) IV 15 mg every 6 hours until bone marrow recovers and mucosal ulceration resolves	Sustains folate cycle blocked by methotrexate Can also be given orally in some circumstances
	Glucarpidase 50 units/kg IV over 5 minutes	Cleaves methotrexate to non-cytotoxic metabolites Discuss with a poison information centre or hospital pharmacy regarding access
Opiates	Naloxone IV 0.01 mg/kg up to 0.2 mg then 0.01 mg/kg/h as needed	Direct receptor antagonist

POISON	ANTIDOTES	COMMENTS
Organophosphates and carbamates	Atropine IV 0.05 mg/kg. Double the dose every 5 min until target endpoints reached	Blocks muscarinic effects
	Pralidoxime IV 15 mg/kg up to 1g, over 15–30 min then 10 mg/kg/hr up to 250 mg/hr	Reactivates cholinesterase; not indicated for carbamate poisoning. Routine use is not recommended based on recent evidence, seek clinical toxicologist advice before considering use
Paracetamol	N-acetylcysteine Refer to local guidelines	Restores glutathione-inhibiting metabolites
Potassium	Calcium chloride IV 10%, 0.14 mmol/kg up to 6.8 mmol (0.2 mL/kg up to 10 mL) OR Calcium gluconate IV 0.13 mmol/kg up to 6.6 mmol (0.6 mL/kg up to 30 mL) Repeat after 10 minutes if required Furosemide 1–2 mg/kg IV Short-acting insulin 0.1 units/kg IV plus Glucose 10% 2.5 mL/kg IV by slow injection plus Sodium bicarbonate IV 1 mmol/kg (max 50	Antagonises cardiac effects (immediate) Decreases serum potassium (rapid marked effect); monitors serum glucose

POISON	ANTIDOTES	COMMENTS
	mmol) over 5–10 minutes plus Salbutamol nebulisation 2.5 mg to 5 mg	
	Resonium oral or rectal 0.5–1 g/kg	Adsorbs potassium (slow effect)
Sulfonylureas and other drugs causing hypoglycaemia	Glucose 0.5–1.0 g/kg IV followed by Octreotide subcutaneously 2 micrograms/kg 8 hourly for at least 24 hours OR 2 µg/kg IV load, followed by 1 µg/kg/hr for at least 24 hours	Monitor serum glucose frequently Refractory hypoglycaemia from sulfonylureas and quinine; inhibits insulin release
Tricyclic antidepressants	Sodium bicarbonate IV 1–2 mmol/kg titrated to a narrowing of the QRS complex and aiming for a blood pH between 7.45 and 7.55	Reduces cardiotoxicity due to sodium channel blockade, indicated for QRS widening >120 ms and terminal R wave in aVR. Dose not to exceed 6 mmol/kg
Valproic acid	L-carnitine IV 100 mg/kg (maximum 6 g) IV as loading dose, followed by 50 mg/kg (maximum 3 g) every 8 hours until improvement	Limited evidence to support use, but can be considered if significant valproate toxicity, i.e cerebral oedema, metabolic acidosis and hepatotoxicity May need haemodialysis or haemofiltration at very high levels

---

BAL , British anti-Lewisite; *IM* , intramuscular; *IV* , intravenous; *SC* , subcutaneous.

The time of presentation after ingestion, as well as the dose, determines the management. If the presentation is within 2 hours of ingestion, administration of activated charcoal may be all that is required, pending a serum paracetamol level. In contrast, if presentation is greater than 8 hours after ingestion, administration of the antidote according to serum paracetamol level takes precedence. For example, in Australia and New Zealand, acetylcysteine is administered intravenously as a 2 bag regime:200 mg/kg acetylcysteine in 7 mL/kg (up to 500 mL) 0.9% sodium chloride or 5% glucose over four hours followed by 100 mg/kg in 14 mL/kg (up to 1000 mL) 0.9% sodium chloride or 5% glucose over 16 hours.[13]

Initial paracetamol levels should be obtained at 4 hours from ingestion and acetylcysteine treatment should be determined via the Rummack-Matthew Nomogram. If the initial paracetamol level is double that of the nomogram the second bag of acetylcysteine should be 200 mg/kg over 16 hours.

Patients who have taken sustained-release preparations at doses greater than 10 g or 200 mg/kg should not have treatment based on the paracetamol level. Treatment should include activated charcoal up to 4 hours after ingestion. Acetylcysteine infusion should also be commenced as a 2-bag regime. If the overdose is 30 g or > 500 mg/kg the second bag should also be 200 mg/kg of acetylcysteine.

Prior to the end of an acetylcysteine infusion, a paracetamol level and alanine transaminase (ALT) should be performed. Acetylcysteine should continue if the paracetamol level remains >10 mg/L or ALT is >50U/L or increasing in cases where the initial ALT >50 U/L.[13]

If hepatic function worsens despite antidote treatment, liver transplantation may be required.

Iron

Small quantities of elemental iron (>60 mg/kg) are potentially toxic to children.[11] The initial effects are gastrointestinal, which may include gastric erosion, followed sometimes by an interval before cardiovascular failure occurs at 6–24 hours and then followed by multiorgan failure (including encephalopathy) and hepatic and renal failure up to some 48 hours after ingestion. Research has suggested that clinical symptoms are best used to guide clinical management as due to the accidental nature of iron ingestion in children suspected doses are a poor predictor of clinical outcome.[27] In addition to general supportive measures, specific management should include an abdominal x-ray to determine if unabsorbed tablets are present. Overdoses of greater than 60 mg/kg may be an indication for whole bowel irrigation after consultation with a toxicologist. Chelation therapy with desferrioxamine (see Table 99.2) should be guided by the serum iron level and the clinical status.

Caustic Substances (Dishwasher and Laundry Detergents)

Laundry detergents are presented as colourful liquids, powders or tablet blocks. [28] Unfortunately, pharyngeal and oesophageal irritation, burns or corrosion may occur with their ingestion. There may be simultaneous ocular and dermal toxicity.

These recently available liquid laundry detergent pods and capsules are sometimes alkaline and more toxic than traditional laundry products. Oral contact causes neurological obtundation, seizures, pulmonary oedema and aspirational lung disease while eye contact causes conjunctivitis and keratitis. [28–30]

Due to the significant morbidity and mortality associated with laundry pod exposure in the paediatric population, significant public health and legislative changes have occurred around the world addressing packaging to deter the visual appeal of these pods, together with changes to the structure of the pod itself to reduce the overall chance of poisoning. Despite these changes, it must be noted that the concentration of detergent within these pods is still significant when compared with other forms of laundry detergent, and consideration of ingestion or skin or ocular exposure should still be suspected if the child has any concerning symptoms. [29, 30]

Any child presenting with a history of ingestion of a caustic substance should have a medical assessment and observation. Ongoing pain, even in the absence of burns to the lips or mouth requires consideration of endoscopic investigation for potential oesophageal burns.

Envenomation

Children are subject to envenomation by a wide variety of terrestrial creatures, including snakes, scorpions, spiders, bees, ants and wasps (see Chapter 106 for adult envenomation). Marine envenomation is mainly caused by jellyfish and stinging fish and only occasionally by venomous octopuses. The clinical manifestations and management of envenomation include the following considerations:

1. A history of envenomation may not be forthcoming when a young child, unsupervised, is bitten by a snake, particularly of the elapid genus, whose fang marks may not be evident. The diagnosis should be suspected in a child who presents with sudden onset of neurological signs and coagulopathy,

with or without non-specific symptoms of vomiting, nausea or headache. Similarly, a diagnosis of spider envenomation in a child should be among the causes considered for a painful skin lesion.

2. The clinical effects of envenomation may be more pronounced in a child compared with an adult for the simple reason of their smaller body mass in relation to injected venom.
3. The dose of an antivenom is not reduced.

The resuscitative management, physical examination and laboratory tests for paediatric poisoning, for the most part, align closely with similar principles of care in the poisoned adult. However, special considerations exist around sourcing a detailed history from the caregiver about potential agents and the timing of ingestion. Management should involve an early multidisciplinary approach to ensure the child and family receive timely and appropriate care that limits potential morbidity and mortality.

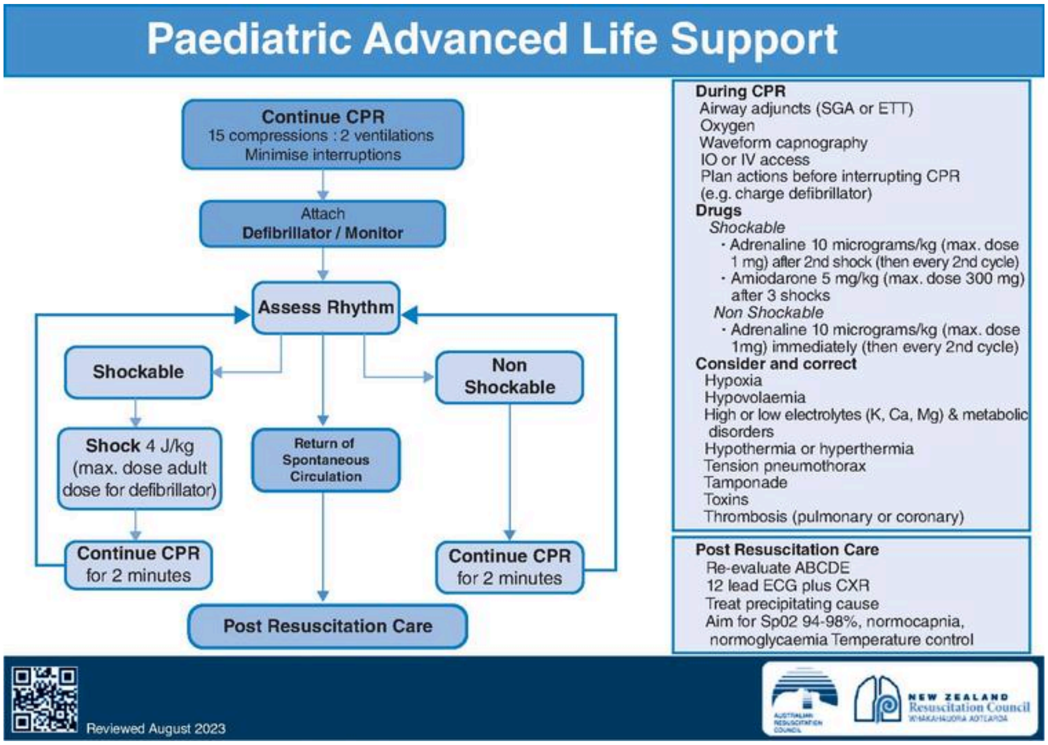
Paediatric cardiopulmonary resuscitation

Andrea S. Christoff and Gabrielle A. Nuthall

Introduction

Cardiopulmonary resuscitation (CPR) for infants and children is described. The essentials of advanced paediatric life support are outlined for the infant and child (Fig. 100.1). Recommendations are based on guidelines published by resuscitation councils, [1–2] which are derived from evaluation of the science of resuscitation by the International Liaison Committee on Resuscitation (ILCOR) in 2023. [3]



Continue CPR
15 compressions : 2 ventilations
Minimise interruptions
Attach
Defibrillator / Monitor
Assess Rhythm
Shockable
Non Shockable
Shock 4 J/kg (max. dose adult dose for defibrillator)
Return of Spontaneous Circulation
Continue CPR for 2 minutes
Continue CPR for 2 minutes
Post Resuscitation Care

Paediatric Advanced Life Support

During CPR
Airway adjuncts (SGA or ETT)
Oxygen
Waveform capnography
IO or IV access
Plan actions before interrupting CPR
(e.g. charge defibrillator)

Drugs
Shockable
- Adrenaline 10 micrograms/kg (max. dose 1 mg) after 2nd shock (then every 2nd cycle)
- Amiodarone 5 mg/kg (max. dose 300 mg) after 3 shocks

Non Shockable
- Adrenaline 10 micrograms/kg (max. dose 1mg) immediately (then every 2nd cycle)

Consider and correct
Hypoxia
Hypovolaemia
High or low electrolytes (K, Ca, Mg) & metabolic disorders
Hypothermia or hyperthermia
Tension pneumothorax
Tamponade
Toxins
Thrombosis (pulmonary or coronary)

Post Resuscitation Care
Re-evaluate ABCDE
12 lead ECG plus CXR
Treat precipitating cause
Aim for Sp02 94-98%, normocapnia, normoglycaemia Temperature control

Reviewed August 2023

The flowchart is titled Advanced Life Support for Infants and Children. The top section outlines the initial step, including start C P R with instructions for 2 breaths and 15 compressions, minimising interruptions. The next step is to attach a defibrillator or monitor and then assess the rhythm, positioned at the centre. From here, the chart branches into shockable or non-shockable. The shockable pathway leads to administering a shock at 4 joules per kilogram, followed by 2 minutes of C P R. The non-shockable path also advises C P R for 2 minutes. Both paths return to reassessing circulation. The right section details actions during C P R, including airway management, oxygen, and drug doses. It also lists conditions to consider and correct, including hypoxia or hypovolemia. Post resuscitation care recommendations are provided, which include reevaluating A B C D E and managing temperature. There is a Q R code and the logos of the Australian Resuscitation Council and New Zealand Resuscitation Council at the bottom.

FIG. 100.1 Advanced life support for infants and children. *CPR* , Cardiopulmonary resuscitation. (Reproduced with permission from Australian Resuscitation Council, Melbourne.)

This chapter is intended for hospital-based medical and nursing personnel. It outlines the current Paediatric Resuscitation Council guidelines and complements Chapters 30 .

Definitions

CPR practices for paediatric patients are based upon a combination of physiology, physical size and age,

- *Infants are those outside the newborn period and less than 1 year of age*
- *Children are those 1 year of age to 18 years old*
- *Paediatric resuscitation guidelines should be used for anyone who 'appears to be a child' and adult guidelines should be used for anyone who appears to be an adult, there is no exact science around this transition point, and it is always better to commence chest compressions rather than delay.*

Prevention

Cardiorespiratory arrest in children is usually preceded by a period of recognisable deterioration and is often predictable and may be preventable. If deterioration is recognised and treated early, in-hospital cardiac arrest (IHCA) arrest may be prevented. Paediatric rapid response systems – medical emergency team or rapid response team, may help to reduce the incidence of cardiac arrest in hospitalised infants and children. At present there is no clear evidence to suggest rapid response systems decrease the incidence of IHCA in paediatric patients. [1]

Epidemiology

More than 20,000 infants and children suffer from cardiac arrest per year in the United States. [4] The majority of IHCA occur in an intensive care setting. Not unexpectedly, survival from out-of-hospital cardiac arrest (OHCA) is less than IHCA. However, OHCA survival outcomes are better with high-quality CPR delivered by a trained bystander at the scene and when dispatch-assisted CPR (DA-CPR) is provided. [4] Approximately 11% of paediatric OHCA patients survive hospital discharge, the outcomes vary by age with infants having lower survival rates, 4.9% for infants versus 17% for adolescents. In 2015 the incidence of paediatric IHCA was 12.7 events per 1000 infant and child hospital admissions with an overall survival of approximately 40%. [5] There is international variability in reporting metrics for long-term survival and follow-up for OHCA and IHCA. A favourable neurologic outcomes in children have been reported in up to 47% of survivors hospital discharge. [4-7]

The most common cause of paediatric cardiac arrest is hypoxaemia leading to terminal bradycardia and asystole. Infants and children are less likely to arrest from cardiac causes or a primary arrhythmia with the exception of infants and children with congenital heart disease. The aetiology of paediatric cardiac arrest varies with age:

- Sudden unexplained death in infancy (SUDI)
- Congenital heart disease
- Respiratory failure
- Septic shock
- Cardiomyopathy
- Myocarditis
- Trauma
- Toxin ingestion/overdose

Paediatric Chain of Survival

Cardiac arrest care has focused on the management of arrest events, high-quality CPR, early defibrillation and effective teamwork. [4] Paediatric cardiac arrest survival rates have plateaued, and the emphasis is on prevention of cardiac arrest and early recognition of deterioration. With a focus on the early management of post-cardiac arrest syndrome which is associated with low cardiac output state, end-organ hypoperfusion and reperfusion injury. Accurate multimodal neuro-prognostication helps guide clinical decision making and family conversations. [8] The chain of survival has been updated to emphasise the importance of recovery and survivorship. [4]

Basic Life Support [1]

Assessment of Airway and Breathing

Initial effective bag-mask ventilation (BMV) is a sufficient and necessary prerequisite for successful paediatric resuscitation. Bags of appropriate sizes should be available for infants and children. On determining that an infant or child is not responsive to stimulation, airway opening manoeuvres and breathing assessment should be performed. The most common cause of airway obstruction in unconscious patients is the tongue. Airway opening manoeuvres should be performed which include head tilt, chin lift and jaw thrust. If a cervical spine injury is suspected, maintain inline precautions and avoid using the head tilt or chin lift manoeuvre. Insertion of an oropharyngeal airway may be necessary to facilitate BMV.

Following the establishment of an airway, assess the adequacy of breathing by inspection of chest wall and abdomen and listening/feeling for exhalation of air. If adequate breathing is identified place the patient in the lateral recovery position.

If breathing is inadequate, then BMV should be commenced. The current recommendation is for two initial rescue breaths. Lack of chest rise may signify an inappropriate size/or seal of the mask or obstruction of the airway requiring repositioning and adjunctive airway opening manoeuvres.

For the unresponsive infant or child with foreign body airway obstruction, commence CPR immediately. Remove any visible foreign body with airway opening manoeuvres to provide breaths. Do not perform blind finger sweeps.

Assessment of Circulation

If the infant or child is unresponsive with no signs of life chest compressions should be commenced immediately. The ‘pulse check’ has been removed from CPR guidelines for the layperson due to the inability to reliably check pulse. Early effective bystander CPR and dispatch assisted (DA-CPR) may be associated with improved outcomes. For health care professionals pulse palpation may be attempted (carotid, brachial and femoral). However, if a pulse cannot be detected within 10 seconds chest compressions should be commenced.

CPR Technique

For infants and children compressions delivered at a rate of 100–120 per min to achieve 1/3 diameter of the chest (4 cm <1 year and 5 cm 1–8 years) with complete recoil and minimal interruptions (<10 seconds pauses). A compression:ventilation ratio of 15:2 should be maintained by healthcare providers and if unable to deliver rescue breaths, compression-only CPR is reasonable. Chest compression technique varies by age and size of the infant or child. For infants with a single rescuer, two fingers on the sternum or two thumbs placed below the inter-nipple line. The recommended technique for an infant when two rescuers are providing CPR is the two-thumb-encircling technique. The thumb encircling technique requires compressor to oppose thumbs together in the centre of the chest below the nipple line, encircle hands around the infant’s chest and use thumbs to compress over the lower third of the sternum. Systematic reviews suggest that this technique may improve CPR quality when compared to the two-finger technique, for depth. [3] For children, the use of a one- or two-hand technique is reasonable. For infants, if the compressor is unable to achieve the recommended guideline depth, a one-hand technique may be required. During IHCA the use of ‘CPR mode’ should be activated on beds, alternatively, placement of a backboard underneath the infant or child may be used to improve chest compression depth.

Rates of Compression and Ratio of Compression to Ventilation

In hospitals (with two or more rescuers), the ratio of compression:ventilation for infants and children should be 15:2. After every 15 compressions, a pause should allow the delivery of two breaths with any type of mask ventilation. The aim should be to achieve 100–120 compressions/min. If ROSC is achieved, but respiration remains inadequate, avoid hyperventilation. If there is an advanced airway in place continuous breaths should be maintained for infants and children at 20–30 breaths/min.

Advanced Life Support

The rapid recognition of cardiac arrest and initiation of high-quality CPR is crucial to improve paediatric cardiac arrest survival. Infants and children are more likely to suffer from hypoxic cardiac arrest compared to a primary cardiac event. Prioritising adequate ventilation while commencing compressions is key. High-quality CPR is more likely to achieve ROSC and the five main elements are (1) optimal chest compression rate, (2) adequate compression depth for age, (3) complete chest recoil between compression, (4) minimise compression interruptions and (5) avoid hyperventilation.[4, 9, 10] CPR feedback or prompt devices are intended to improve CPR quality, probability of ROSC and survival from cardiac arrest. CPR feedback devices may improve compression depth, rate and recoil within a system that utilises resuscitation bundles of care for continuous quality improvement initiatives.[4] Invasive and non-invasive cardiac monitoring may help augment CPR quality. Haemodynamic resuscitation targets include diastolic blood pressure and end-tidal CO_2 ($ETCO_2$).[3-4]

The use of haemodynamic monitoring techniques may be used for IHCA to guide and assess the quality of CPR provided.

Reversible causes of cardiac arrest should be sought and treated during resuscitation, considering hypoxia, hyperkalaemia, hypothermia, hypovolaemia, thrombus, tamponade, tension pneumothorax and toxins (four Hs and four Ts).

Advanced Airway Intervention During CPR

Airway management and effective ventilation are fundamentals of paediatric resuscitation. The method of BMV while performing chest compressions requires a pause in compressions to deliver breaths. This may induce barotrauma and is a risk for aspiration.

Advanced airway interventions, endotracheal intubation (ETI) or supraglottic airway (SGA) insertion may improve ventilation and allow for continuous compressions without interruptions for ventilation. However, the act of intubation during CPR may be challenging and success is dependent on the skill of the operator.

There is a lack of evidence to support a recommendation to establish an advanced airway during IHCA.[4,9] There may be specific cohorts or populations when early advanced airway is beneficial, including prolonged cardiac arrest events.

During cardiac arrest, it is reasonable to manage ventilation with BMV instead of establishing an advanced airway until ROSC.[4,9]

Intubation during CPR may result in a prolonged interruption in chest compressions and malposition of the endotracheal tube in the oesophagus or mainstem bronchus.

Immediately after intubation, tracheal placement of the tube should be confirmed by capnography or colorimetric CO_2 detection. Capnography is preferred because it also affords ongoing assessment of CPR quality and adequate ventilation. Excretion of CO_2 needs effective pulmonary blood flow and ventilation of the lungs. If unable to detect $ETCO_2$ during a perfusing rhythm, endotracheal tube dislodgement must be considered. If the ETT is correctly located in the trachea and $ETCO_2$ is not detected, the quality of CPR is likely inadequate and the compression depth should be adjusted to meet age-related guidelines for depth.

Cuffed ETTs are recommended over uncuffed ETTs for intubating infants and children. When a cuffed ETT is used the size, position and cuff inflation pressure must be considered. The correct tube size should allow a small leak on the application of moderate pressure but also ensure adequate lung inflation.

The routine use of cricoid pressure during intubation does not reduce the risk of regurgitation and aspiration. Cricoid pressure during BMV may obscure landmarks and prevent intubation success. If cricoid pressure is used discontinue compressions if there is interference with adequate ventilation or speed of intubation.

Supraglottic airway (SGA) may be used to establish and maintain an airway in the spontaneously breathing patient and for emergency relief of upper airway obstruction, but they have a limited role during CPR. The role of a SGA in the provision of mechanical ventilation remains uncertain. Like BMV, they do not protect the airway from aspiration. Although insertion of an SGA is easier to learn than endotracheal intubation, training should not replace mastery of BMV. SGA is not suitable for long-term use or during transport when endotracheal intubation is preferred. [11], [12]

Drug Administration During CPR

Adrenaline is used during cardiac arrest to restore spontaneous circulation by optimising coronary perfusion. The arrest dose of adrenaline used in paediatrics is 10 mcg/kg. For non-shockable rhythms, the first dose of adrenaline should be administered as soon as possible. [3] Subsequent doses of adrenaline should be administered every 3–5 minutes until ROSC is achieved. [1] For shockable rhythms, adrenaline is administered after the second shock. Anti-arrhythmics reduce the risk of recurrent ventricular fibrillation after defibrillation. The routine administration of calcium and sodium bicarbonate is not supported by current data. [4] However, there are specific circumstances when use is indicated, for example, drug toxicity or hyperkalaemia. Medication dosing for infants and children is weight-based and often reliant on estimated weight during emergency situations.

Intravenous (IV) access should be attempted immediately. If IV access cannot be achieved rapidly (within 60 seconds), intraosseous (IO) access should be obtained. The IO route has been used for patients of all ages and provides rapid, safe and reliable access to the circulation and is an adequate route for any drug and/or fluid administration.

Management of Bradyarrhythmia

The most common cardiac arrest rhythms in children are non-shockable rhythms, bradycardia, pulseless electrical activity and asystole.

Bradycardia associated with haemodynamic compromise, even if the pulse is palpable, may be a sign of impending cardiac arrest. Bradycardia with a heart rate of less than 60 beats/min and cardiopulmonary compromise requires immediate attention to ventilation and oxygenation. If bradycardia with haemodynamic instability is noted despite effective ventilation and oxygenation, CPR should be commenced immediately. If bradycardia is secondary to increased vagal tone, atropine should be administered. If bradycardia transiently improves with the management of hypoxia, then give IV/IO adrenaline. If bradycardia is secondary to atrioventricular block and is unresponsive to routine measures and adrenaline then emergency pacing may be attempted (transcutaneous, epicardial, oesophagal or transvenous)

Management of Ventricular Fibrillation (VF) and Pulseless Ventricular Tachycardia (pVT)

For shockable rhythms, the priority is high-quality CPR and early defibrillation. Perform CPR until the shock is ready to be delivered. A single shock followed by immediate chest compressions for 2 minutes, is recommended for infants and children. The initial energy dose for VF or pVT is 2–4 J/kg of monophasic or biphasic energy followed by immediate resumption of chest compressions without pausing to analyse the rhythm. If VF or pVT persists, subsequent single shocks of 4 J/kg are given, each followed by 2 minutes of chest compressions. Adrenaline is administered after the second shock and either amiodarone or lignocaine may be used for refractory VF or pVT.

The dose of amiodarone is 5 mg/kg IV or IO as a bolus, which may be repeated to a maximum of 15 mg/kg. If amiodarone is not available, administer lignocaine in a dose of 1 mg/kg IV or IO.

Defibrillators should have paediatric pads/paddles. Selectable energy levels should enable the delivery of doses 0.5–4 J/kg. The nearest joules to the calculated weight-based dose should be selected (round up the joules dose). The doses for monophasic and biphasic energy are the same.

Use the largest paddles or self-adhering electrode pads that will fit on the infant or child's chest while maintaining adequate separation between pads/paddles. Placement of pads is either in the antero-lateral or anterior-posterior position.

Monophasic and biphasic automated external defibrillators (AEDs) with attenuated energy doses (approximately 50 J or less) may be used for children 1–8 years of age. Adult energy doses of 150–200 J may be used in children older than 8 years of age or 25 kg body weight. Although AEDs are not recommended for use in infants as they may not reliably distinguish VF from tachycardia and hence pose a risk of harmful DC shock, in the situation of a 'shockable' rhythm with no cardiac output, an AED with dose attenuation may be used. If that is not available, an adult AED may be used.

Rescuers should be aware of the risk of inadvertent shock to themselves and colleagues during the operation of defibrillators. They should ensure that they have no physical contact with the patient directly or indirectly at the time of electrical discharge.

In a hospital setting with trained healthcare providers, a manual defibrillator is recommended when a shockable rhythm is identified. The first DC shock should be delivered within 90 seconds with compressions continuing during the charging phase and hands off chest for delivery of shock.

Extracorporeal Cardiopulmonary Resuscitation (ECPR)

Initiation of extracorporeal life support (ECLS) during CPR is very resource intense and may be considered for IHCA if the setting has available resources, which may include an established ECMO programme, protocols/guidelines, equipment and personnel with expertise in rapid deployment of ECLS. [13]

The ECMO cannulation strategy during CPR depends on the context, the postcardiotomy patient will have ECMO initiated via central cannulation and after chest open compressions will transition to internal cardiac massage. If peripheral neck cannulation is the preferred technique CPR should continue with the goal to minimise pauses in compressions to less than 10 seconds to optimise coronary perfusion and minimise periods of low flow state.

Management of Tachyarrhythmia

Regular narrow complex tachyarrhythmia (QRS duration 0.0 seconds or less is commonly caused by re-entrant circuits). Children also are prone to ectopic atrial tachycardia and atrial fibrillation.

Supraventricular Tachycardia

SVT is the most common spontaneous arrhythmia in childhood and infancy. It may cause life-threatening hypotension. It is usually re-entrant with a rate of 220–300 per minute in infants. The QRS complex is usually narrow, making it difficult sometimes to discern from sinus tachycardia. However, whereas sinus tachycardia is a part of other features of illness, SVT is a singular entity, and whereas the rate in sinus tachycardia is variable with activity or stimulation, it is uniform in SVT. In both rhythms, a P-wave may be discernible. SVT with aberrant conduction (QRS >0.08 seconds) may resemble VT. Relative treatment of these tachyarrhythmias are summarised in APLS website and AHA guidelines as appropriate to your region. [4]

If SVT is haemodynamically stable (adequate perfusion and blood pressure), initial treatment should be vagal stimulation. For infants and young children, when applicable, 'face submerged in ice bath is often effective'. Older children may be guided to perform a Valsalva manoeuvre (e.g. blowing through a narrow straw). If the patient is ventilated, apply vagal stimulation by tracheal or pharyngeal suction. If vagal stimulation is unsuccessful, give adenosine.

Any alternative drug treatment for haemodynamically stable SVT should be in consultation with expert advice. In addition, stable SVT unresponsive to vagal stimulation and drug therapy may be treated with synchronised DC shock (cardioversion) in a dose of 0.5–1.0 J/kg after consultation with experts.

SVT may cause severe hypotension or pulselessness, in which case synchronised DC shock (cardioversion) at 0.5–1.0 J/kg should be given immediately, progressing to 2 J/kg if necessary. While preparations are made to give DC shock, vagal stimulation and adenosine (IV or IO) may be tried provided they do not delay cardioversion.

Management of Wide Complex Tachyarrhythmia with Pulse

Wide complex tachycardia (QRS duration greater than 0.09 seconds) with a pulse is rare in children. It may originate from SVT with aberrant conduction or VT. For infants and children with hemodynamically stable wide complex tachycardia expert consultation is recommended prior to commencing anti-arrhythmic agents. However, infants and children with wide complex tachyarrhythmia and hemodynamic compromise should be treated with direct synchronised cardioversion, which should be provided urgently.

Hemodynamically stable VT may be treated with an anti-arrhythmic agent such as amiodarone or procainamide after expert consultation. If torsade de pointes is present, magnesium IV or IO may be used.

Post-Cardiac Arrest Care (PCAC)

Post-Cardiac Arrest Syndrome: Monitoring, Care and Treatment

Return of circulation following successful resuscitation results in the complex physiology of post-cardiac arrest syndrome (PCAS). The key components of this are (1) post-cardiac arrest brain injury, (2) post-cardiac arrest myocardial dysfunction, (3) systemic ischaemia/reperfusion response, and (4) the persistent precipitating pathophysiology of the cardiac arrest.[14], [15] To maximise survival to hospital discharge with good neurological outcome, these components must all be anticipated, recognised and treated.

Targeted temperature management (TTM) requires continuous measurement of core temperature, and for infants and children who remain comatose after either OHCA or IHCA it is reasonable to use TTM, either 32–34°C followed by 36–37.5°C or only TTM of 36–37.5°C.[3], [16-17]

Blood pressure management should ideally be via continuous arterial line pressure monitoring, so hypotension can be rapidly identified and treated. Any episode of hypotension is associated with worse neurological outcomes.[18], [19] Post ROSC a systolic blood pressure of greater than the tenth percentile for age should be maintained by intravenous fluid administration and/or vasopressor therapy depending on underlying patient physiology.[4, 8, 15, 18-19, 23]

For management of oxygenation and ventilation, PaO_2, $PaCO_2$ and saturations should be monitored. Target normoxia and/or saturations of 94%–99% (or child's normal saturations), and avoid hypocapnia (or aim for a $PaCO_2$ that is appropriate for the child's underlying condition).[9, 15]

Both non-convulsive and convulsive seizures are common in the post-ROSC phase and if resources allow, continuous electroencephalography (EEG) monitoring is recommended, as without this non-convulsive seizure and non-convulsive status cannot be detected. While there is not sufficient evidence to prove treatment of seizures improves outcomes, both convulsive and non-convulsive seizures are associated with worse outcomes and it is reasonable to treat seizures in consultation with experts.[4, 9, 20-21]

The underlying cause of the cardiac arrest should be identified, and pathophysiology treated. In addition, any complications such as organ dysfunction should be promptly treated to prevent further secondary brain injury (Fig. 100.2).

Review, discuss, adjust and confirm at every shift:

1. Optimize Ventilation and Oxygenation
    - ☐ Maintain advanced airway; protect ventilation
    - ☐ Maintain normoxia (SpO$_2$ 94-98%)
    - ☐ Wean FiO2 if saturation is >98%
    - ☐ Maintain PaO$_2$ targets for cyanotic patients
    - ☐ Maintain normocapnia (waveform capnography)
2. Assess for and Treat Persistent Shock
    - ☐ Identify and Treat Possible Contributing Factors →
3. Circulation
    - ☐ Maintain reliable intravenous access
    - ☐ Maintain invasive blood pressure monitoring
    - ☐ Optimize hemodynamics
        - ○ Aim for *age-specific* BP Targets*
        - ○ Monitor MAP, Lactate, ScvO$_2$, CO/CI, urine output
        - ○ *Hypo*tensive Shock: *consider* epinephrine, dopamine, norepinephrine, vasopressin
        - ○ *Normo*tensive Shock: *consider* dobutamine, dopamine, epinephrine, milrinone
    - ☐ Fluid (crystalloid) – restore normovolemia
    - ☐ Perform echocardiography
4. Target Temperature Management
    - ☐ Constant temperature for 24-48 hrs:
        - ○ *Hypo*thermic: 32°C – 34°C
        - ○ *Normo*thermic: 35°C – 37°C
    - ☐ Prevent and treat fever for at least 96 hrs
    - ☐ Prevent and treat shivering
5. Monitor and Treat
    - ☐ Need for Sedation / Paralysis
    - ☐ Agitation
    - ☐ Seizures: EEG, sedation, anticonvulsants
    - ☐ *Hypo*glycemia
    - ☐ *Hyper*glycemia if >__________mm/dL
    - ☐ Blood gas, serum electrolytes, calcium, magnesium
6. Avoid prognostication for at least 72h post ROSC

- ☐ **H**ypovolemia
- ☐ **H**ypoxia
- ☐ **H**ydrogen ion (acidosis)
- ☐ **H**ypoglycemia
- ☐ **H**ypo-/hyperkalemia
- ☐ **H**ypothermia
- ☐ **T**ension pneumothorax
- ☐ **T**amponade, cardiac
- ☐ **T**oxins
- ☐ **T**hrombosis, pulmonary
- ☐ **T**hrombosis, coronary
- ☐ **T**rauma

Notes to Team:

v.28Apr2016

The P R E P Checklist and Communication Form for Post Resuscitation Evaluation and Planning includes sections for patient information such as name, age, M R N, room number, and details of the most recent arrest, including time of return of spontaneous circulation, date, and time. The top portion features a table for recording time, temperature, S P O 2, S B P, M A P, and E T C O 2, referred to as target ranges, with multiple datelines. Below, the form provides instructions divided into six main categories, including Optimize Ventilation and Oxygenation, Assess for and Treat Persistent Shock Circulation, Target Temperature Management, Monitor and Treat, and Avoid prognostication for 72 hours post R O S C. Additional sections include checklist options for medical conditions, including hypovolemia, hypoxia, hyperglycaemia, hypothermia, and others. There is also a Notes to Team section, and a box explaining minimum blood pressure targets based on age, and specific guidelines on temperature management and the treatment of shock conditions.

Stopping Cardiopulmonary Resuscitation

The decision to stop resuscitation efforts in paediatric patients after cardiac arrest is challenging. It should be based on an assessment of the child's underlying clinical status, the response to resuscitation efforts along with the following factors. Duration of resuscitation, initial and subsequent rhythms, the underlying cause, the duration between the onset of the cardiac arrest and the initiation of resuscitation and the family's wishes.

It is important to note that the decision to stop resuscitation should not be made by a single individual but rather by a team of experienced healthcare professionals, including physicians, nurses and other specialists, after following established guidelines and protocols. Additionally, the decision-making process may vary depending on local laws, cultural considerations and institutional policies.

Ultimately, the goal is to provide the best possible care for the paediatric patient while being mindful of the medical futility of continued resuscitation when the chances of a successful outcome are exceedingly low.

Family members should be kept informed and given the option to be present during the resuscitation of their infant or child. When family members are present during a resuscitation it is helpful to have a designated staff member to support the family.

Post-Resuscitation Staff Management

Cardiac arrests in a hospital setting are often unexpected and test the readiness and resilience of skilled teams within an organisation. Support for staff members involved in a resuscitation is essential and conducting debrief sessions after a cardiac arrest should be encouraged. Structured, data informed, post-resuscitation debriefing is an opportunity for clinicians to review resuscitation practices and identify areas for improvement in CPR quality and team performance. A recent study suggests that the implementation of an interdisciplinary post-cardiac arrest debriefing programme is associated with improved CPR quality and higher survival rates with favourable neurologic outcome after index IHCA events.[22]

Poisoning and drug intoxication

Tamishta Hensman, Brendan R. Murfin and Nicholas A. Barrett

Acute poisoning remains a common medical emergency. Approximately 14% of those presenting to the hospital are admitted to a critical care unit.[1] In the majority of cases, poisoning is unintentional and involves multiple agents. In-hospital mortality is low (<0.5%)[1,2] but notably higher in intentional exposures.[1] There are specific antidotes available for a small number of poisons and drugs, however, in most intoxications supportive care is the main management strategy, allowing time for the intoxicant to be metabolised and excreted.

Clinical toxicology remains an experience-based specialty; consequently, many recommendations are based on a small literature of case reports or on pharmacological principles rather than on controlled clinical studies. There is significant regional variation in protocols and clinical guidelines, therefore consultation with local toxicology specialists is a key component of management in the critical care environment. Further resources include position statements published by extracorporeal treatments in poisoning workgroup (EXTRIP) and guidelines published by the UK National Poisons Information Service (TOXBASE) and Therapeutic Guidelines.

General Principles

The cornerstones of the management of poisoned patients are resuscitation, supportive care and monitoring. A risk assessment is important to determine what complications may arise and the level of intervention required. Measures to reduce absorption or enhance elimination and specific antidotes may be indicated in some cases. In more acute situations, these actions often have to be carried out simultaneously.

Resuscitation

In acutely poisoned patients who are unconscious, dentures should be removed and the oropharynx cleared of food and vomit. Tracheal intubation and airway protection are almost always necessary when a patient tolerates insertion of an oropharyngeal airway – perhaps the only exception to this rule is patients who have taken gamma-hydroxybutyric acid (GHB) or gamma-butyrolactone (GBL) where consciousness can be reliably predicted to return within 2–4 hours. Inadequate spontaneous ventilation, determined clinically or by arterial blood gas (ABG) analysis, obviously requires ventilatory support. Venous access should be established, and a circulatory assessment must be made. Basic observations, including blood pressure, pulse rate, temperature, peripheral perfusion and urine output, should be recorded.

Risk Assessment

A risk assessment should encompass the drug type, dose and formulation, time of ingestion, past medical history, age, weight, clinical examination and consider the clinical course so far. Much of this information may not be available.

The clinical examination should include looking particularly for needle marks or evidence of previous self-harm. The Glasgow Coma Scale, designed for head-injured patients, is frequently used, but descriptive documentation of the degree of impaired consciousness is much more valuable. In an unconscious patient with no history available, the diagnosis depends upon excluding other common causes of coma and circumstantial evidence. Specific attention should be paid to the temperature, pupil size, blood pressure, respiratory and heart rate, as these may help to restrict the list of potential toxins (Box 101.1). Patients should also have a detailed neurological examination, preferably before the administration of any muscle relaxants, documenting the presence/absence of abnormal tone and reflexes, spontaneous/inducible clonus and/or ocular clonus.

Box 101.1

Clinical effects of the common poisons

Convulsions

Tricyclics, isoniazid, lithium, amphetamines, theophylline, carbon monoxide, phenothiazines, cocaine, organophosphates

Skin

Bullae: barbiturates, tricyclics
Sweating: salicylates, organophosphates, amphetamines and cocaine

Pupils

Constricted: opioids, organophosphates
Dilated: hypoxia, hypothermia, tricyclics, phenothiazines and anticholinergics

Temperature

Pyrexia: anticholinergics, tricyclics, salicylates, amphetamines and cocaine
Hypothermia: barbiturates, alcohol and opioids

Cardiac rhythm

Bradycardia: digoxin, beta-blockers and organophosphates
Tachycardia: salicylates, theophylline and anticholinergics
Arrhythmias: digoxin, phenothiazines, tricyclics and anticholinergics

Investigations

Important initial investigations include the following:

- *Urinalysis* : keep a sample for later analysis if required. Although rapid reaction dipsticks are available to screen for common drugs of abuse/recreational drugs by immunoassay, their routine use is not recommended owing to false-positive results, detection of metabolites rather than parent drug and/or cross-reactivity with prescription and over-the-counter medicines.
- *Basic biochemistry* : given the dependence on renal elimination for many drugs, acute or chronic renal insufficiency will alter patient management. It is also helpful to establish a baseline for both renal and liver function.
- *ABG analysis* : metabolic and/or respiratory acidosis is most common. Aspirin may initially cause a respiratory alkalosis, which in more significant ingestions can be followed by a metabolic acidosis or a combined picture of a respiratory alkalosis/metabolic acidosis. Metabolic alkaloses are unusual.
- *Anion gap* $=([\mathrm{Na}^+]+[\mathrm{K}^+])-([\mathrm{Cl}^-]+[\mathrm{HCO}_3^-])$: it is normally 10–14 mmol/L. Ethanol, methanol, ethylene glycol, metformin, cyanide, isoniazid or salicylates are the most frequent causes of a high anion gap metabolic acidosis in clinical toxicology.
- *Imaging* : inhalation of gastric contents is not uncommon; chest X-ray changes consistent with aspiration should be sought. A CT Brain is also commonly performed to exclude differential diagnoses for those who present with an altered conscious state.
- *Drug levels* : these are rarely helpful except in specific poisonings. They include paracetamol, salicylates, iron, digoxin, alcohol and lithium. It is important to note that, for most poisonings, drug concentrations guide rather than dictate treatment.

Gastrointestinal Decontamination

Decontamination techniques comprise methods to remove the toxin from the gastrointestinal tract to reduce absorption and enhance elimination. A number of historical techniques have been abandoned due to clinical safety concerns, including ipecacuanha-induced emesis [3] and gastric lavage. [4]

Activated Charcoal (AC)

AC remains the most prevalent method of decontamination. [5] Owing to its large surface area and porous structure it is highly effective at adsorbing many toxins with few exceptions. Exceptions include elemental metals, pesticides, alcohols including ethanol, strong acids and alkalis and cyanide.

Indications for AC include exposures where serious toxicity is anticipated and the drug is known to bind to activated charcoal. It has the greatest benefit when administered within 1–2 hours of drug ingestion and up to 4 hours after modified release preparations and massive ingestions.

Whilst the overall risk of adverse events is low, vomiting may occur and therefore AC should not be given to patients with a decreased GCS at risk of aspiration. Intubation specifically for AC administration is rarely required.

Repeated doses of AC can increase the elimination of some drugs by interrupting their entero-enteric and enterohepatic circulation. [6] Indications for repeated dose AC are shown in Box 101.2 . It should also be considered in patients who have ingested a modified or slow-release preparation or significant salicylate ingestions; in these situations, multiple doses of AC are being administered to reduce absorption rather than enhance elimination. AC is given in 50 g doses for adults and 0.5–1 g/kg (max 50 g) for children. It commonly causes vomiting; therefore consider giving an antiemetic prior to administration. Multiple doses can be associated with constipation so patients should be given an appropriate laxative. Repeated doses are given at 2 to 4-hourly intervals until it is clinically indicated to stop. Obtunded patients with any airway compromise should have their airways secured prior to the use of AC.

Box 101.2

Drug intoxications where multiple dose-activated charcoal may be beneficial

- Carbamazepine
    - Phenytoin
    - Colchicine
    - Amanita phalloides
- Theophylline
- Digoxin
- Quinine
- Phenobarbital
- Dapsone
- Sustained-release preparations

Whole Bowel Irrigation

This is a method of gut decontamination that is indicated for a limited number of poisons. [7] Whole bowel irrigation involves the administration of a non-absorbable polyethylene glycol solution to cause a liquid stool and reduce drug absorption by physically forcing contents rapidly through the gastrointestinal (GI) tract. Polyethylene glycol preparations are still occasionally used in surgical units for ‘bowel preparation’ prior to surgery. It may have a role in treating large ingestions of drugs that are not absorbed by AC. Indications include large ingestions of iron or lithium, ingestion of drug-filled packets/condoms (‘body packers’), and large ingestions of sustained-release or enteric-coated drugs (e.g. theophylline or calcium-channel blockers), and it is most effective if started within 4 hours of ingestion. Whole bowel irrigation may lead to significant shifts in fluid and electrolyte composition; hence they should only be considered in patients in whom careful monitoring can be instituted.

Enhancing Drug Elimination

In the overwhelming majority of patients who present after an overdose, gut decontamination techniques and supportive care are all that is required. In a limited number of acute poisonings, it may be necessary to consider methods to enhance elimination.

Urinary Alkalinisation

Urinary alkalinisation (previously termed *forced alkaline diuresis*) is useful in promoting the excretion of drugs that are weak acids. It acts by increasing the proportion of the drug contained in the form of a non-lipid soluble charged salt, which is then trapped in the tubular lumen and subsequently excreted. The term ‘urine alkalinisation’ emphasises that urine pH manipulation is the prime objective of treatment; the terms ‘forced alkaline diuresis’ and ‘alkaline diuresis’ should be discontinued. It is first-line treatment in moderate to severe salicylate poisoning, [8] and may have a role in phenobarbital, chlorpropamide and methotrexate poisonings.

Alkalinisation is initiated by giving intravenous 8.4% sodium bicarbonate (the joint American and European toxicologists' statement recommends 225 mL over 1 hour in adults whilst other guidelines suggest 1–2 mmol/kg bolus over 10 minutes). Further bicarbonate is given if required to achieve a urine pH of 7.5–8.5; this can be performed with further boluses or with a continuous infusion. Care must be taken to ensure the potassium does not fall rapidly, and the urine pH should be measured every 15–30 minutes. Therapeutic endpoints include urine pH of 7.5, resolving clinical symptoms and resolution of any toxicant-associated biochemical abnormalities (i.e. metabolic acidosis).

Extracorporeal Elimination

Numerous extracorporeal techniques are potentially available to aid drug removal in the poisoned patient, as well as correct metabolic and biochemical abnormalities as a result of the poisoning. These include plasmapheresis, haemodialysis, haemofiltration, haemodiafiltration and haemoperfusion. There are limited data on drug clearance by these techniques in the literature and it is not possible to extrapolate from one system to the other, but when extracorporeal removal is indicated, intermittent haemodialysis is generally recommended as the first line.

An international multidisciplinary working party, EXTRIP, has published a number of recommendations for extracorporeal treatments in various poisonings and advises against their use in calcium-channel blockers, isoniazid, methotrexate, tricyclic and digoxin poisoning. [9-16]

Extracorporeal techniques should be considered for specific drugs, in patients with significant renal impairment (and therefore delayed clearance), when there are clinical features or markers of severe toxicity or there is failure to respond to full supportive care coupled with poisoning by a drug that can potentially be removed (see Box 101.3). The use of extracorporeal techniques is probably worthwhile only if total body clearance is increased by at least 30%. Although some drugs have improved clearance with haemodialysis rather than haemofiltration, ultimately using filtration rates of greater than 50–100 mL/kg per hour is likely to be as effective as other approaches and is widely available in intensive care units. Haemoperfusion is rarely available but may have a role in hepatically cleared drug poisonings.

Box 101.3

Drug intoxications where extracorporeal elimination may be helpful

Paracetamol
Barbiturate
Salicylate
Atenolol, sotalol [a]
Carbamazepine
Ethylene glycol, methanol
Gabapentin/pregabalin [a]
Lithium
Metformin
Phenytoin
Theophylline
Valproic acid

[a] Indicated in cases of co-existing renal impairment.

Lipid Emulsion Therapy

Intravenous lipid emulsion (ILE) using 20% Intralipid is recognised as an effective treatment for local anaesthetic-induced cardiovascular collapse with a recommended initial dose of 1.5 mL/kg over 1 minute, followed by an infusion of 15 mL/kg/h. If cardiovascular instability persists give a repeat bolus dose of 1.5 mL/kg every 5 minutes (two further doses) and increase the rate to 30 mL/kg/h. The maximum cumulative dose is 12 mL/kg.[17] The mechanism for benefit is not entirely clear but is thought to relate either to the formation of an enlarged lipid sink, which may help to remove the offending drug from target tissues or as an energy substrate for a shocked myocardium. Based on the lipid sink hypothesis, ILE has been considered a potential treatment for severe acute poisoning from a range of lipophilic drugs.[18,19] There is an increasing number of case reports where ILE has been used in non-local anaesthetic poisonings including amitriptyline,[20] quetiapine[21] and verapamil[22] amongst others, however, it is not routinely recommended in these poisonings at this time. There have been reports of recurrence of toxicity after initial dosing with ILE, as well as complications such as pancreatitis.[23] For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered. It is important to remember that the significant lipaemia following ILE therapy may rapidly render the oxygenator non-functional and an urgent oxygenator change may be required if this occurs.

Continued Supportive Therapy

General supportive care of the unconscious unstable patient is required. This includes monitoring and provision of organ support including extracorporeal membrane oxygenation when necessary, as well as fluid balance, correction of electrolytes, initiation of nutritional support and prompt treatment of nosocomial infection. Overall, despite the significant initial physiological disturbance, this group of patients usually has a good outcome.

Specific Therapy of Some Common or Difficult Overdoses

This section emphasises only those features that may aid clinical diagnosis or prognosis. These are always intended to support those measures described under general principles.

Amphetamines Including ‘Ecstasy’, 3,4-Methylenedioxy-Methamphetamine (MDMA)

Clinical Features

Symptoms of mild overdose include sweating, dry mouth and anxiety. Although the majority of ecstasy patients are dehydrated, a proportion have hyponatraemia from drinking water to excess; therefore it is important to measure serum sodium and electrolytes early in the patient’s management. More severe features include tachycardia, hypertonia, hyperreflexia, hallucinations and hypertension. Supraventricular dysrhythmias may follow with coma, convulsions and the risk of haemorrhagic stroke. A hyperthermic syndrome may develop with hyperpyrexia leading to rhabdomyolysis, metabolic acidosis, acute renal failure, disseminated intravascular coagulation (DIC) and multiple organ failure. Where hyperthermia is suspected it is important that core body temperature (e.g. oesophageal, blood or rectal) is measured to accurately record the degree of hyperthermia. [24]

Treatment

AC should be considered up to 2 hours post-ingestion. Benzodiazepines are useful for agitated or psychotic patients and may have a central effect in reducing tachycardia, hypertension and hyperpyrexia. If benzodiazepines fail to control hypertension, other classes of antihypertensives should be started, such as alpha-blockers or direct vasodilators. Beta-blockers, even specific ones, should not be used due to the risk of unopposed alpha stimulation and subsequent hypertension or coronary vasospasm developing. This occurs in approximately 1 in 200 patients and it may be worth considering drugs with alpha antagonism or mixed alpha/beta antagonism such as labetalol.[25] It should be noted that most patients are fluid-depleted rather than fluid-overloaded, and measurement of sodium concentrations should be undertaken early in fluid resuscitation. Hypertonic saline may rarely need to be considered in severe hyponatraemia, particularly if seizure activity is present. Hyperthermia should be treated in the standard manner, including administration of cold (4°C) IV fluids, general cooling measures and benzodiazepines. For patients whose temperature remains elevated (particularly above 39°C), consider PO/NG (oral/nasogastric) cyproheptadine (a 5HT$_{2A}$ antagonist) – the initial dose is 12 mg followed by 2 mg every 2 hours until temperature and other symptoms have settled. Benzodiazepines and cyproheptadine should also be used in those patients with evidence of moderate/severe serotonin toxicity.[26] Dantrolene has also been described in treating MDMA-associated hyperthermia.[27] Additional methods for cooling, such as external and internal cooling devices or those used for maintenance of body temperature post-cardiac arrest, can be considered for rapidly reducing body temperature.

Benzodiazepines

Clinical Features

Overdose is common, but clinical features are not usually severe unless complicated by other central nervous system (CNS) depressant drugs (such as alcohol), pre-existing disease or the extremes of age. Toxicity commonly produces drowsiness, dysarthria, ataxia and nystagmus. Paradoxical agitation and confusion can occur less commonly.

Treatment

AC can be given if patients present within 1 hour of ingestion, yet supportive treatment is usually all that is required. Flumazenil is a specific antagonist that is not licensed for use in poisoning and may be dangerous due to the risk of significant cardiovascular (ventricular tachycardia) and neurological (status epilepticus) toxicity, as well as precipitating withdrawal in benzodiazepine-dependent patients. [28] Its use is therefore not recommended.

Beta-Blockers

Clinical Features

There is a wide variation in the individual response to beta-blocker overdose. Those with cardiac disease and/or renal failure are more at risk of complications. Hypotension and bradycardia predominate and are often refractory to standard resuscitation measures. The degree of heart block can range from a prolonged PR interval through to complete heart block and asystole. Cardiogenic shock and pulmonary oedema are not uncommon. [29] Hypoglycaemia, bronchospasm, coma and seizures may also occur and distinguish beta-blocker from calcium-channel blocker poisoning.

Treatment

AC should be considered up to 2 hours post-ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. There is limited evidence to support the use of atropine in patients who have bradycardia and hypotension and it is often ineffective. If treatment with IV fluids for hypotension fails, glucagon (up to 10 mg IV as an initial bolus) may be trialled before commencing high-dose insulin euglycaemic treatment, as described in the calcium-channel blocker section. Intralipid has a role in propranolol overdose and may be helpful in other beta-blocker poisonings.

Supportive measures include avoidance of hypocalcaemia and magnesium replacement. Vasoactive medications may be required based on the clinical presentation; milrinone may be more effective due to its phosphodiesterase rather than adrenergic pathway but is limited by hypotension. High-voltage capture is often required if temporary pacing is used. Other measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation should be considered if the simpler methods are not able to stabilise the patient. [30]

Butyrophenones (Including Haloperidol)

Clinical Features

Drowsiness and extrapyramidal effects are the most common. Rarely hypotension, QT prolongation, arrhythmias and convulsions develop. Serious toxicity is uncommon.

Treatment

AC should be considered up to 2 hours post-ingestion, otherwise, treatment is supportive. Extrapyramidal symptoms can be treated with procyclidine (5–10 mg IV/intramuscularly in adults) or diazepam (10–20 mg in adults). Intralipid therapy has been reported as a successful strategy in one case report, and although it cannot be recommended for routine use, it may be an option to consider in the event of a life-threatening overdose.

Calcium-Channel Blockers

Clinical Features

The cardiac effects of these drugs predominate in overdose, particularly hypotension and atrioventricular block, although reflex tachycardia occurs with nifedipine. Hypotension occurs owing to peripheral vasodilatation and negative inotropy. The therapeutic selectivity of actions is not typically seen in overdose. Presentation is generally less severe with dihydropyridine forms. Severe toxicity may occur in patients who initially appear well when sustained-release preparations have been ingested.

Treatment

AC should be considered up to 2 hours post-ingestion and multiple-dose charcoal in patients who have ingested sustained-release preparations. Treatment remains supportive; however, IV calcium chloride (10 mL of 10% solution) is often given in patients who remain hypotensive despite fluid administration. Further boluses and/or an infusion should be administered as guided by the clinical response. In those patients requiring multiple doses and/or an infusion, monitor the serum calcium concentration to ensure it remains below 3 mmol/L. Atropine is often used for bradycardia to varied effect, and occasionally cardiac pacing may be necessary (high capture thresholds may be required). In those with persistent hypotension not responding to IV fluids and calcium, high-dose insulin euglycaemic therapy, is indicated. [31] An initial bolus of 1 unit/kg of short-acting insulin should be administered with 25–50 mL of 50% dextrose, followed by an infusion of 0.5–2 units/kg/h short-acting insulin; higher doses may be required in severely compromised patients. Careful monitoring of blood glucose and serum potassium should be undertaken, with replacement as necessary. There is anecdotal evidence that increasing glucose requirements suggests that cardiovascular toxicity is starting to diminish. Intralipid has been described in verapamil poisoning and may be considered in other calcium-channel blockers where hypotension is refractory to standard management. For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered. [30]

Carbamazepine

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. Carbamazepine undergoes enterohepatic recirculation leading to a prolonged overall half-life and is metabolised to an active metabolite.

Clinical Features

Nystagmus, ataxia, tremor and fits are common; however, in severe overdose, fluctuating coma and severe tachycardia or bradycardia may occur. Plasma concentrations of carbamazepine and the active metabolite can be measured, although they do not correlate well with toxicity. Life-threatening toxicity typically occurs with plasma concentrations greater than 40 mg/L (170 nmol/L).

Treatment

Multiple-dose AC is indicated in large ingestions or symptomatic patients and may help elimination even if initiated several hours after the overdose. Further measures are based on the clinical course. Currently, intermittent haemodialysis (IHD) is recommended in severe poisoning with intermittent haemoperfusion (IPF) and continuous renal replacement is considered acceptable if IHD is not available. [12]

Carbon Monoxide

Haldane first described symptoms of carbon monoxide (CO) toxicity in 1919 and the mechanisms of toxicity remain unclear. Smokers may have up to 10% of their haemoglobin bound to CO (i.e. carboxyhaemoglobin [COHb]), without deleterious effects. Whereas coma and/or COHb levels greater than 40% always indicate serious poisoning, delayed deterioration can occur in their absence. Affinity of CO for haemoglobin is approximately 240 times that of oxygen.

Clinical Features

Neurological signs vary from mild confusion through to seizures and coma. A history of loss of consciousness should always be sought and may be the only indicator of significant poisoning. ST segment changes may be present on electrocardiogram (ECG). In the absence of respiratory depression or aspiration, PaO_2 will be normal. It is essential that SaO_2 is measured directly by a co-oximeter, and not calculated. Cherry-pink skin is seen only in textbooks; cyanosis is far more common.

Treatment

After basic resuscitative measures, high-flow oxygen (up to 100% if possible) should be administered and continued until the COHb level is less than 5%. This sometimes takes up to 24 hours. Hyperbaric oxygen (HBO), although often used, remains controversial. There have been eight randomised controlled trials of HBO versus normobaric oxygen. Unfortunately, many of these are of poor quality, and it is not possible to show any statistical benefit of HBO in reducing neurological sequelae in 1 month. [32] Considering the frequently encountered logistical difficulties in transferring an unconscious patient to an HBO centre, it cannot be routinely recommended based on the data currently available.

Cocaine

Clinical Features

The clinical features of acute cocaine toxicity are similar to those seen in amphetamine toxicity. There is the additional risk of cocaine-related vasospasm, which can lead to ischaemia in any vascular bed but is of particular significance from a cardiac and cerebral perspective. Cocaine-related myocardial ischaemia is due primarily to coronary artery vasospasm; additional mechanisms included increased myocardial oxygen demand due to increased heart rate, decreased vasodilators (nitric oxide), increased vasoconstrictors (endothelin) and increased platelet aggregation.[33] Cocaine additionally blocks myocardial fast sodium channels leading to arrhythmias including SVT and VT.

Treatment

The treatment of the common unwanted effects related to cocaine is the same as those seen with amphetamines. In terms of myocardial ischaemia, there are some differences between the management of this compared with classical atherosclerotic-related ischaemia. Patients should be treated with oxygen and aspirin; low-molecular-weight heparin and glycoprotein IIb/IIIa inhibitors should not be routinely used due to the increased risk of cerebral haemorrhage in significant hypertension. Vasodilators (e.g. sublingual, buccal or IV nitrates) should be given early in an attempt to reverse coronary artery vasospasm, although care should be taken if there is a significant tachycardia due to the risk of a reflex tachycardia leading to an increased heart rate. Benzodiazepines should be administered to reduce sympathetic nervous system stimulation, thereby reducing myocardial oxygen demand by reducing the heart rate, as well as potentially causing coronary artery vasodilatation through peripheral cardiac benzodiazepine receptors. Beta-blockers are contraindicated as they can lead to unopposed alpha stimulation leading to worsening hypertension; in addition, they can worsen cocaine-related coronary artery vasospasm. Other measures in those who fail to respond include other vasodilators (e.g. calcium-channel blockers and alpha-blockers) and/or primary angiography and angioplasty/intraluminal drug treatment. Ventricular tachycardias warrant treatment with sodium bicarbonate boluses (50–100 mmol) to counter the sodium-channel blockade and consideration of a lignocaine infusion. For patients with ongoing cardiovascular instability or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered. [30]

Cyanide

Clinical Features

Severe toxicity is rapidly fatal; however, features include coma, respiratory depression, hypotension and metabolic acidosis. More moderate features include brief loss of consciousness, convulsions and vomiting. Rescuers must ensure that they do not get contaminated themselves. Expert advice is usually required in the management of these patients owing to the risk of significant toxicity.

Treatment

Inhaled amyl nitrate and 100% oxygen may well have been given at the scene since it is present in ‘cyanide antidote kits’. Following this, there are a number of options:

1. Pre-hospital hydroxycobalamin 70 mg/kg or 5 g IV over 15 minutes.
2. In-hospital management of moderate to severe poisoning may require a second dose of 5 g hydroxycobalamin. The Australian Resuscitation Council suggests a third dose if required.
3. In severe poisoning, the addition of sodium thiosulphate 12.5 g at 1.25 g/min is recommended. If signs of poisoning continue, half the original dose may be repeated. [34]
4. Patients with metabolic acidosis should be given sodium bicarbonate.

Digoxin

Clinical Features

Toxicity may result from ingestion of as little as 2 mg and lethal doses are >10 mg in adults and >4 mg in children. More commonly toxicity results from taking too high a daily dose and/or a reduction in renal elimination. Gastrointestinal symptoms are common, and presentation may be with weakness, confusion or visual changes. Any cardiac arrhythmia may occur (except for rapidly conducted atrial arrhythmias). Ventricular arrhythmias are more common in chronic toxicity and in those with chronic heart disease; bidirectional VT is rare. Severe poisoning can produce hyperkalaemia and hypotension; hyperkalaemia is a poor prognostic sign with a potassium of >5.5 mmol/L associated with a 100% mortality risk if not treated with digoxin-specific antibodies (Fab). Factors that may exacerbate or precipitate toxicity include drugs that inhibit p-glycoprotein efflux pump (amiodarone, azithromycin, ticagrelor to name a few), hypercalcaemia, hypomagnesaemia, hypokalaemia and acidosis.

Treatment

AC should be considered up to 2 hours post-ingestion and multiple-dose charcoal may be effective by interrupting enterohepatic recirculation of the drug. A digoxin serum level may be helpful although it does not equate to the total body burden – it is helpful to confirm poisoning. Patients with hyperkalaemia should be initially managed with insulin–dextrose therapy and sodium bicarbonate may be used as adjunctive therapy. The use of calcium in these patients may be associated with adverse cardiac outcomes and is therefore avoided where possible.

Digoxin-specific Fab fragments should be administered in all cases of severe toxicity. Indications include life-threatening arrhythmia, cardiac arrest and potassium >5 mmol/L. Fab may also be helpful in acute ingestions >10 mg in adults or >4 mg in children, evidence of end-organ dysfunction, serum digoxin concentration >12 ng/mL and moderate-to-severe gastrointestinal symptoms. [35] Total serum digoxin level may rise after therapy as it takes both digoxin and Fab fragments into account. Empiric treatment is 200–400 mg (5–10 vials) for adults. For patients with ongoing cardiogenic shock or intractable arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered.

Gamma-Hydroxybutyric Acid and Gamma Butyrolactone

Clinical Features

In moderate to high ingestion, coma, convulsions, bradycardia, hypotension and severe respiratory depression can be seen, and other CNS depressant drugs potentiate the effects. Most patients who present to the hospital merely require supportive care, and even those who present in a coma are often awake within 2–4 hours; very few require intensive care. [36]

Treatment

Management is largely supportive; intubation is often not indicated even in those with significantly reduced levels of consciousness as airway reflexes tend to be maintained. [36] Computed tomography scanning should be considered in those with evidence of head injury, focal neurological signs or failure to wake after 1–2 hours. It is important before discharging a patient to determine whether they are potentially dependent users (daily use) and therefore at risk of withdrawal. Expert advice on the management of these patients should be sought.

Iron

Clinical Features

Iron poisoning classically has four phases:

- *Phase 1:* initial GI symptoms secondary to direct corrosive action on gastric mucosa. Symptoms include vomiting, haematemesis, abdominal pain and lethargy.
- *Phase 2:* latent asymptomatic phase.

- *Phase 3:* systemic iron toxicity with mitochondrial failure and hepatic necrosis.

  Acute liver failure, renal failure with oliguria and hypotension secondary to gastrointestinal fluid losses and vasodilation. A high anion gap metabolic acidosis ± ketosis and lactic acidosis may occur.
- *Phase 4:* GI strictures several weeks after initial ingestion due to the scarring after direct corrosive effects.

The duration of phases 1 and 2 is dependent on the dose of iron ingested; some patients with very large ingestions may progress straight to a combined phase 1/3 presentation. Serum iron concentration is helpful in patient management.

Treatment

In those patients who present with features of severe iron poisoning, deferoxamine (also known as desferrioxamine mesilate) should be commenced. It acts by chelating iron into complexes that are renally excreted and are started at an initial rate of 15 mg/kg/h. The maximum licensed dose is 80 mg/kg/day; however, these patients may require more prolonged treatment and appropriate advice should be sought. Haemodialysis is helpful in eliminating the deferoxamine – iron complexes and correcting acidosis. For those presenting within 6 hours without severe symptoms, the management can be guided by a serum iron concentration 4–6 hours after ingestion (<55 µmol/L does not require treatment, >90 µmol/L treatment is recommended, 55–90 µmol/L treatment may be required depending on whether the concentration is not falling and/or the clinical condition of the patient). For those presenting more than 6 hours after presentation without severe features, the serum iron concentration is not as helpful in determining the need for treatment; expert advice should be sought for these patients.

Isoniazid

Clinical Features

Severe toxicity is characterised by coma, respiratory depression, hypotension and convulsions resistant to conventional treatments, and may result from doses greater than 80 mg/kg. Protracted convulsions can cause rhabdomyolysis and acute renal failure.

Treatment

AC should be considered for large ingestions seen within 2 hours. Management of convulsions is initially benzodiazepines (IV 10–20 mg diazepam, or IV 4 mg lorazepam); those who fail to respond should be treated with 1 g of pyridoxine per gram of isoniazid ingested to a maximum of 5 g. Barbiturates, such as thiopentone, should be used as second-line therapy for patients with seizure activity, which does not respond to benzodiazepines. Phenytoin should not be administered, as it is ineffective and isoniazid inhibits the metabolism of phenytoin.

Lithium

Clinical Features

There are two types of overdose: acute in lithium-naïve individuals, and chronic in those on long-term lithium treatment. For the latter, this may be secondary to an intentional overdose or due to other factors such as dehydration or use of interacting drugs (e.g. non-steroidal anti-inflammatory drugs [NSAIDs], angiotensin-converting-enzyme [ACE]-inhibitors and thiazide diuretics). Symptoms of toxicity can be divided as follows:

- *Mild:* nausea, vomiting, fine tremor, polyuria, weakness
- *Moderate:* confusion, urinary and faecal incontinence, myoclonic twitches/jerks, hypernatraemia and hyperreflexia
- *Severe:* coma, renal failure, convulsions and cardiac arrhythmias

Treatment

Lithium concentrations should be measured on arrival in chronic cases and then repeated every 4–6 hours; for acute overdoses, lithium concentrations should be measured 6 hours after ingestion and then every 4–6 hours.

Patients should be adequately rehydrated, which may help with any renal impairment. Extracorporeal elimination is recommended if renal function is impaired and the lithium concentration is >4.0 mEq/L or in the presence of a decreased conscious state, seizures or life-threatening dysrhythmias (regardless of lithium concentration). Hypernatraemia may also delay clearance. [37] It may also be helpful if the serum lithium is >5.0 mEq/L, if confusion is present or if the expected time to obtain serum lithium <1.0 mEq/L is > 36 hours. [10] Intermittent haemodialysis is the preferred method, with continuous RRT an acceptable alternative if IHD is unavailable.

For patients with ongoing cardiovascular instability or intractable life-threatening arrhythmias, measures including extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should be considered. [30] Seizure activity should be treated with benzodiazepines (first line) or barbiturates (second line). Phenytoin should not be used for seizure control.

Methanol and Ethylene Glycol

Clinical Features

Methanol and ethylene glycol are relatively non-toxic themselves, but their ingestion is a medical emergency because of their metabolism (following a latent period of 12–18 hours) to formic acid and glycolic acid, respectively. These toxic metabolites account for metabolic acidosis, ocular toxicity, renal failure and mortality that are occasionally seen. Mild features include dizziness, drowsiness and abdominal pain. When treatment is delayed, metabolic acidosis develops with drowsiness, coma and convulsions. The osmolal gap (the difference between measured and calculated osmolality) initially is elevated but then falls as the methanol or ethylene glycol is metabolised; the anion gap increases as the toxic metabolites build up.

Treatment

AC does not adsorb either methanol or ethylene glycol. The metabolic acidosis should be treated with sodium bicarbonate and the serum electrolytes measured. Ethanol prevents formation of the toxic metabolites and previously it has been the most established treatment; its dosing is complex and it requires 1- to 2-hourly blood ethanol measurement and adjustment of the treatment. Additionally, it can cause significant CNS depression, necessitating critical care admission. Fomepizole (4-methypyrazole) has now become the antidote of choice; it is a twice-daily weight-based infusion without the need for specific monitoring and is not associated with neurological depression. [38] The initial dose is 15 mg/kg over 30 minutes, followed by a twice-daily infusion of 10 mg/kg for the next four doses and then increased to 15 mg/kg per treatment dose until treatment is no longer required. Ongoing management after the initial loading dose often requires the involvement of clinical/medical toxicology services to facilitate ethylene glycol/methanol concentration measurement and interpretation of the results. The EXTRIP work group recommends concurrent extracorporeal treatment for severe methanol poisoning defined by the presence of coma, seizures, new vision deficits, metabolic acidosis pH less than 7.15, persistent metabolic acidosis despite adequate supportive measures and antidotes, a serum anion gap greater than 24 mmol/L or serum methanol levels greater than (1) 700 mg/L (21.8 mmol/L) in the context of fomepizole therapy; (2) greater than 600 mg/L (18.7 mmol/L) in the context of ethanol treatment; and (3) 500 mg/L (15.6 mmol/L) in the absence of alcohol dehydrogenase blocker. [39] It is important to remember with both ethanol and fomepizole that, should extracorporeal treatment be required, not only will the toxic alcohol be removed, but so too will the antidote; modifications to treatment regimens will be required.

Non-Steroidal Anti-Inflammatory Drugs

Clinical Features

NSAIDs are commonly ingested in an overdose; symptoms tend to be mild and consist of GI symptoms. GI haemorrhage is not commonly reported in an acute overdose of NSAIDs (apart from those due to Mallory–Weiss tears). Convulsions can occur but are usually associated with mefenamic acid (up to 10%–15% of patients). Large ingestions of NSAIDs can be associated with metabolic acidosis and/or renal impairment [40] and rarely hepatocellular injury. [41] Patients who do not develop symptoms within 4 hours are unlikely to experience delayed toxicity.

Treatment

AC can be given for large ingestions that are seen within 2 hours of the overdose. Convulsions should be treated with a benzodiazepine. Although there is no indication for routine use, those patients with symptoms of GI irritation can be treated with a short course of an oral proton pump inhibitor. Metabolic acidosis should be treated with sodium bicarbonate and other measures as indicated. Supportive care and appropriate investigation are required for patients with renal impairment.

Opioids

Opiates are the leading cause of accident-related death in the United States of America and Australia.

Clinical Features

Overdose is characterised by pinpoint pupils, drowsiness, shallow breathing and ultimately respiratory failure. Methadone is associated with prolongation of the QT interval and torsades de pointes.

Treatment

AC may be effective for oral ingestions; otherwise, treatment is supportive. Naloxone 100–200 µg boluses should be given IV and increased as titrated to clinical response. In patients who fail to respond to 2 mg, alternative diagnoses should be considered. Those who respond may require repeat doses, particularly where a long-acting or sustained/modified release preparation has been ingested; an infusion of naloxone may be required in these patients. Intubation and mechanical ventilation are required if respiratory failure is not rapidly reversed by naloxone.

Organophosphates

Organophosphates are found in a number of chemicals, including insecticides and fertilisers. Given its wide use in agriculture and farming, the incidence of poisoning is high particularly within parts of Asia and Africa, with an estimated fatality rate of 10%–20% for intentional ingestions. [42] Agents are easily absorbed through inhalation or the topical route.

Clinical Features

The primary mechanism of action is inhibition of acetylcholinesterase. Symptoms include central neurological effects such as agitation, seizures and loss of consciousness. Muscarinic effects encompass miosis, salivation, bradycardia, bronchospasm and diarrhoea whilst nicotinic effects may result in tachycardia, hypertension and sweating. Actions at the neuromuscular junction result in muscle weakness and may lead to flaccid paralysis. Clinical features may be delayed up to 12 hours post-exposure.

Treatment

Organophosphate poisoning is primarily a clinical and historical diagnosis, however, plasma and red cell cholinesterase tests can be used to confirm exposure. Decontamination is important to prevent ongoing poisoning and clothing should be removed. Off-gassing may occur from exhalation of vapours – personal protective equipment is recommended for health care providers prior to decontamination and if ventilator equipment is required, this should not be reused as organophosphates are absorbed in rubber and plastics and may persist for a significant time. [43]

Benzodiazepines are helpful in the supportive care of agitation and seizures. Atropine counters the effect of acetylcholine stimulation and should be given as a 0.02 mg/kg bolus repeated every 5 minutes as required. Large doses are often needed. [43] Pralidoxime binds to the organophosphate-acetylcholinesterase complex and reverses it. Early administration is key as it must be given before the complexes irreversibly age. An initial 2-gram bolus may be followed by an infusion for 24 to 48 hours. [44]

Paracetamol

Paracetamol toxicity is a result of an increased metabolism of its toxic metabolite, *N*-acetyl-*p*-benzoquinonimine (NAPQI), as normal conjugation pathways are exceeded. This toxic metabolite irreversibly binds to hepatocytes leading to cell death and release of inflammatory and cytotoxic mediators and further hepatocyte death. It remains the most common cause of severe acute liver injury in Western countries.[45] An acute single ingestion of ≥ 10 grams or 200 mg/kg is associated with a risk of acute liver injury; multiple dosing thresholds have been defined for repeated ingestions.

Although IV acetylcysteine administered more than 16 hours after ingestion may not prevent severe liver damage, it should still be given since outcome from paracetamol-induced fulminant hepatic failure is improved.

Clinical Features

Paracetamol poisoning is often asymptomatic in the early stages (the first 24–48 hours); later presentations may be associated with evidence of acute liver injury/failure. Patients with very significant ingestions (initial 4-hour paracetamol concentrations of >800 mg/L) may present in coma with lactic metabolic acidosis – this is a direct effect of the paracetamol.

Treatment

AC should be considered for patients who present within 2–4 hours of potentially ingesting ≥10 g of ≥200 mg/kg.

N-acetylcysteine (NAC) treatment should be commenced if:

- serum paracetamol level is on or over the nomogram treatment line. Multiple treatment graphs exist and vary by region but, generally, start treating at paracetamol levels of 100–150 mg/L at 4 hours.
- presentation is 8 hours after ingestion of ≥10 g or ≥200 mg/kg of immediate release form whilst awaiting pathology results or in settings where paracetamol level is not readily available.
- presentation is greater than 4 hours after ingestion of ≥10 g or ≥200 mg/kg of modified release form.

Traditional NAC regimens involved a 3-bag dose, equal to 300 mg/kg over 21 hours.

Recently published guidelines now recommend the use of a 2-bag NAC regimen, comprising of an initial loading dose of 200 mg/kg over 4 hours, followed by 100 mg/kg over 16 hours; this is associated with significantly reduced adverse reactions when compared to the traditional 3-bag regimen. [46] A modified 12-hour regimen has also been described but is subject to further outcome evaluation. In those patients with evidence of liver injury, the last dose (100 mg/kg over 16 hours) is repeated until the patient's condition and biochemical and haematological results are improving. NAC is associated with a high incidence of non-IgE anaphylactic and hypersensitivity reactions which is likely related to higher blood concentrations of the drug. The two-bag regimen is associated with a lower incidence of these reactions than in traditional protocols. [47]

Disposition

Advice from a poisons information centre or toxicologist should be sought in cases of

- very large overdose (>50 grams or over 1 gram/kg)
- paracetamol level more than triple the nomogram line
- intravenous paracetamol overdoses
- patients with hepatotoxicity (i.e. ALT >1000)
- neonatal paracetamol poisonings

Although severe hepatic injury has a 10% mortality, the majority of patients recover within 1–2 weeks. [48] Referral to a liver transplant centre should be considered if the King's College criteria are met:

- Arterial pH <7.3 after fluid resuscitation
- Or all of
  - INR >6.5 (Prothrombin time >100 seconds)
  - Serum creatinine >3.4 mg/dL (301 mmol/L)
  - Grade 3 or 4 hepatic encephalopathy [49]

Additional features warranting referral to a liver transplant centre include oliguria, lactate >3 mmol/L and hypoglycaemia.[46]

Paraquat

In adults, the lethal dose is 3–6 g (i.e. 15–30 mL of 20% w/v liquid concentrate). The mortality rate in patients ingesting the liquid concentrate is about 45%.[50] The lung is the primary target organ, with the injury being enhanced by oxygen. Peak concentrations are achieved between 0.5 and 2 hours.

Clinical Features

Initial symptoms are GI pain and vomiting with corrosive effects on the mouth, pharynx and oesophagus. Dyspnoea and pulmonary oedema follow within 24 hours, progressing to irreversible fibrosis and death. Cardiac, renal and hepatic dysfunctions are common.

Treatment

Those treating suspected paraquat-poisoned patients should wear appropriate personal protective equipment to prevent secondary exposure. An urgent qualitative urine test (dithionite spot test) should be undertaken to confirm exposure; a confirmatory plasma concentration should be measured in those where positive as this may guide prognosis. Management is largely supportive: analgesia for oropharyngeal burns and other measures as indicated by the patient’s clinical condition. Oxygen therapy can increase the degree and severity of pulmonary fibrosis. Palliative care may be required in those with high paraquat concentrations who fail to respond to treatment. Expert advice should be sought in these patients to determine whether other treatment options including veno-venous extracorporeal membrane oxygenation may be appropriate.

Phenytoin

Clinical Features

Absorption is slow and unpredictable; moreover, maximum serum concentrations may not be achieved until 72 hours after ingestion. After initial nausea and vomiting, neurological symptoms develop including drowsiness, dysarthria and ataxia, and may ultimately progress to seizures. Cardiovascular toxicity is rare unless the overdose has been given intravenously.

Treatment

Most patients require nothing more than supportive measures. There is some evidence from volunteer studies that multi-dose AC can increase the elimination of phenytoin; it is not clear whether this alters the outcome. [51] Extracorporeal removal is indicated if prolonged coma is present or expected and is considered reasonable if prolonged severe ataxia is present or expected. The preferred choice of removal is intermittent haemodialysis with intermittent haemoperfusion an acceptable alternative. [9]

Salicylates (Aspirin)

Moderate toxicity occurs with serum concentrations of 500–750 mg/L (3600–5500 µmol/L) and severe toxicity with concentrations greater than 750 mg/L. Serum concentrations alone do not determine prognosis. The elimination half-life increases significantly with increasing concentrations. Small reductions in pH produce large increases in non-ionised salicylate, which then penetrates tissues.

Clinical Features

Tinnitus, deafness, diaphoresis, pyrexia, hypoglycaemia, haematemesis and hypokalaemia may all occur. Hyperpnoea occurs due to direct stimulation of the medullary respiratory centre as well as uncoupling of oxidative phosphorylation (which causes pyrexia). Coma, pulmonary oedema and acidaemia are reported as more common in fatal cases, which present late.

Treatment

The minute ventilation generated by the patient is rarely able to be matched by mandatory ventilation. For this reason, as well as the risk of rapid changes in arterial pH secondary to short periods of apnoea, intubation is reserved for cases of severe respiratory failure, i.e., bradypnoea. Although multiple-dose AC is not recommended by some experts, most medical toxicologists would recommend its use in large ingestions since concretions of salicylates in the stomach can occur with delayed ongoing absorption. Urinary alkalinisation (see above) decreases the amount of non-ionised drugs available to enter tissues and should be considered in those with moderate/severe toxicity. Extracorporeal techniques are very effective in removing salicylates and correcting acid-base disturbance.[14] They are recommended if salicylate level is > 7.2 mmol/L or > 6.5 mmol/L with impaired kidney function, in the presence of altered mental status or new hypoxaemia requiring oxygen and if standard supportive measures fail.[14] Intermittent haemodialysis is the mode of choice.

Selective Serotonin Reuptake Inhibitors and Serotonin-Noradrenaline Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline. Common serotonin-noradrenaline reuptake inhibitors (SNRIs) are duloxetine and venlafaxine. These drugs have increasingly replaced tricyclic antidepressants (TCA) and generally appear to be much safer in overdose.

Clinical Features

Drowsiness, tachycardia and mild hypertension are the commonest features. Seizures and coma can occur, as well as a serotonin syndrome in 14% of cases.[52] A number of clinical scoring systems for the diagnosis of serotonin syndrome exist, the most accurate being the Hunter criteria (Box 101.4).

Box 101.4

Hunter Criteria for Serotonin Toxicity[53]

Presence of a serotenergic agent plus one of

- Spontaneous clonus
- Inducible clonus and agitation or diaphoresis
- Ocular clonus and agitation or diaphoresis
- Tremor and hyperreflexia
- Hypertonia, temperature >38.0°C and ocular or inducible clonus

Treatment

AC should be considered up to 2 hours post-ingestion, otherwise, treatment is supportive. Benzodiazepines should be used to treat agitated or hyperthermic patients. There are case reports of cyproheptadine being used to treat severe toxicity with SSRIs. [54] In those with hyperthermia, the advice (as mentioned earlier) for amphetamines should be followed in terms of assessment of the hyperthermia and the appropriate management interventions. Drugs known to exacerbate serotonin syndrome should be avoided.

Theophylline

Clinical Features

Acute theophylline poisoning is potentially very serious and severe poisoning carries a high mortality. Toxic effects such as agitation, tremor, nausea, vomiting and sinus tachycardia become evident at less than 30 mg/L (167 µmol/L). Concentrations greater than 60 mg/L (333 µmol/L) in acute poisoning or greater than 40 mg/L (222 µmol/L) in chronic usage frequently result in seizures, malignant ventricular arrhythmias, severe hypotension and death. [55] A key feature is hypokalaemia, which predisposes to arrhythmias and rhabdomyolysis. Measuring plasma theophylline levels confirms the ingestion and may help in deciding elimination methods; in the majority of poisoned patients, they do not aid management. Sustained-release preparations may result in delayed onset and prolonged toxicity.

Treatment

Multi-dose AC should be considered, particularly in those with serum concentrations greater than 40 mg/L. Although hypokalaemia does occur, there is not a total body depletion of potassium, therefore only potassium concentrations of less than 3 mmol/L should be cautiously replaced; monitor for rebound hyperkalaemia. Convulsions should be treated with benzodiazepines and cardiac arrhythmias with beta-blockers in non-asthmatic patients. Vomiting is often severe and requires appropriate antiemetic administration. IHD is recommended in severe poisoning and if not available, IPF and continuous renal replacement therapy (CRRT) are acceptable alternatives. [11]

Tricyclic Antidepressants

Clinical Features

Features include anticholinergic effects such as warm dry skin, tachycardia, blurred vision, dilated pupils and urinary retention. Severe features include respiratory depression, reduced conscious level, cardiac arrhythmias, fits and hypotension. Arrhythmias may be predicted by a QRS duration greater than 100 ms on the ECG; a QRS duration of greater than 160 ms increases the risk of seizures. All forms of rhythm and conduction disturbance have been described, and are not necessarily predicted by the ECG. [56] Amoxapine typically causes features of severe poisoning in the absence of QRS widening. Cardiac toxicity is due mainly to quinidine-like actions, slowing phase 0 depolarisation of the action potential. Other mechanisms include impaired automaticity, cholinergic blockade and inhibition of neuronal catecholamine uptake. Toxicity is worsened by acidaemia, hypotension and hyperthermia. Symptoms usually manifest within 2 hours of reported ingestion, with doses >10 mg/kg considered potentially lethal.

Treatment

After supportive care as outlined above, including multiple-dose AC, continuous cardiac monitoring is essential. Increasing arterial pH to ≥7.45 significantly reduces the available free drug and this may be the best way to avoid TCA toxicity. 8.4% sodium bicarbonate given in 50 mmol boluses achieves this strategy and may improve the outcome.[57] Bicarbonate should probably be given in all cases of QRS prolongation (even in the absence of metabolic acidosis), arrhythmias with associated hypotension or metabolic acidosis; it should also be considered in those with convulsions. It should be monitored with frequent arterial blood gases, aiming for a QRS <140 ms, pH of 7.5–7.55 and sodium <155 mmol/L. If arrhythmias occur, avoid class 1a agents; lidocaine may be best. Intralipid should be considered in patients who remain haemodynamically unstable or have refractory arrhythmias; extracorporeal support with veno-arterial extracorporeal membrane oxygenation or cardiac bypass should also be considered in these cases.[30] Benzodiazepines are the drug of choice for sedation and the treatment of seizures and may prevent the emergence of delirium. Extracorporeal removal is not recommended.[16]

Valproate

Clinical Features

Most overdoses follow a benign course, with nausea, mild drowsiness and confusion. Coma can occur in large ingestions with cerebral oedema. There is the potential for metabolic derangement, including metabolic (lactic) acidosis, hypernatraemia, hypocalcaemia and hypoglycaemia. Hyperammonaemia occurs due to disruption of the urea cycle and is more common in those with pre-existing liver disease.

Treatment

Valproate levels are of little value, except to confirm the ingestion. There is a poor correlation between the depth of coma and the free or total valproate levels. Supportive management is all that is usually required. Although in therapeutic use, valproate is extensively protein-bound, with increasing plasma concentrations there is a saturation of this binding leading to increased free drug; extracorporeal treatment is now recommended with haemodialysis the first choice. IPF and CRRT are acceptable alternatives.[58] Additionally, in those patients with significant overdoses, associated hepatic dysfunction and hyperammonaemia, consider the use of intravenous L-carnitine.

Submersion

Andrew Semark, Alice Young and James P. McCullough

Definitions

Drowning is defined as the process of experiencing respiratory impairment from submersion or immersion in liquid. Drowning events are classified as fatal or non-fatal, whereby a fatal drowning occurs whenever a victim dies at any time, compared to a non-fatal drowning, in which the process of drowning is interrupted. Previous terminology including ‘near drowning’, ‘wet and dry drowning’ and ‘secondary drowning’ are no longer used. Outcomes can be classified as death, morbidity and no morbidity. [1] According to the World Congress on Drowning in 2022, the outcomes from non-fatal drowning may be further categorised into mild, moderate or severe respiratory impairment and morbidity categorised into no morbidity, some morbidity and severe morbidity. [2], [3]

Epidemiology

Drowning remains a significant worldwide public health concern, responsible for an estimated 236,000 deaths per annum. It is the third leading cause of death from unintentional injury, accounting for 7% of all injury-related deaths worldwide. [1] In 2022, Australia reported a total of 339 drowning deaths and a further 686 people experienced a non-fatal drowning. These data represented a 15% increase from 2021 and a 24% increase when compared against the previous 10-year average. [4] Low- and middle-income countries account for over 90% of unintentional drowning deaths and over half of global drownings occur in the WHO South-East Asian Region and the Western Pacific Region, which includes Australia and New Zealand. [1] Individual risk factors associated with drowning include drug or alcohol intoxication, trauma and co-morbid disease, with a population risk association according to age group, geographical location and socio-economic status. The published per capita rates of fatal drownings in developed countries are variable with New Zealand having a higher rate compared to other countries such as Australia, Canada and the United Kingdom. For the past 10 years, the rate in New Zealand has been 1.7 per 100,000 population compared to 1.1 per 100,000 in Australia and 1.3 per 100,000 in Canada. [5]

Drowning Physiology

The physiological changes that occur during drowning are secondary to immersion into water and the aspiration of water and contaminants. A volume of 1–3 mL/kg of aspirated fluid is sufficient to cause respiratory impairment. [6] The response to aspirated fluid is a complex interaction of cutaneous and cardiorespiratory reflexes, integrated with autonomic responses which affect fluid distribution, endocrine function, altered cell membrane ion channel activity and microvascular circulatory changes. [7] A resultant pathophysiological endpoint of tissue hypoxia, manifested by circulatory collapse, severe acute lung injury and cerebral ischaemia being the significant driver of mortality.

Fresh or Saltwater

Both fresh and saltwater aspiration have similar potential to disrupt surfactant and the alveolar-capillary membrane with resultant non-cardiogenic pulmonary oedema and acute respiratory distress syndrome (ARDS) ensuring. There is no clinically significant difference between fresh and saltwater drownings. [6]

Post Drowning Management

Basic Life Support

The principles and approach to basic life support (BLS) and advanced life support (ALS) in drowning patients are crucial in the pre-hospital setting. BLS resuscitation attempts may be commenced in the water with the use of early rescue breaths increasing chances of survival without sequelae three-fold. [8] Isolated respiratory arrest can respond to these rescue breaths. Failure to respond suggests cardiac arrest and thus prompt removal from the water should ensue to enable CPR to commence, noting that chest compressions in the water are futile. Compressions should be commenced if the victim can be rescued onto a boat; however, the quality of resuscitation may be impaired depending on the size of the boat, speed of movement and water conditions, so attempts to return to solid ground should be made. [9]

Persons should be removed from the water in the vertical position to prevent vomiting and airway soiling. Subsequently, they should be managed in the supine position with their head slightly up. Positioning with the head down, to attempt active drainage of the lungs, delays resuscitation attempts and increases the risk of vomiting and subsequently mortality. [10] Basic life support follows the traditional ABC sequence. Airway assessment should be performed by opening the mouth with a chin lift. In adults, the head is tilted and in infants, it remains neutral . [11] Airway management takes priority over cervical-spine immobilisation. Injuries to the spine occur in <0.5% of drownings and immobilisation is only indicated when there is a strong suspicion of injury, such as when the drowning is the result of a diving or water sport-related incident. [12] Rescue breaths should be delivered to all patients who are unresponsive and not breathing normally to address the primary issue of hypoxaemia. [13] The European Resuscitation Council recommends five breaths rather than two as compliance may be impaired. [14] If unresponsive to ventilation alone then CPR should be initiated and should follow standard 30 compressions to 2 breaths. Chest compression-only CPR is strongly discouraged. Chest compression-only CPR fails to address the underlying hypoxic aetiology of the arrest and is unlikely to be successful. [15] Retrieval from the water may result in profound hypotension due to the loss of hydrostatic pressure causing venous pooling. Keeping the patient supine may mitigate some of these pathophysiological changes whilst awaiting further ALS support. Obtaining an automated external defibrillator (AED) should not delay CPR. It should however be sought and attached as early as possible as there will be a small proportion of drowning associated with a shockable rhythm. Although the chest should be dried prior to attaching pads, it is safe to use a defibrillator on a wet surface. [16]

Advanced Life Support

The ALS and ongoing management of a patient post-drowning will depend upon the degree of respiratory and cardiac compromise. The presence of any respiratory distress or abnormal auscultation warrants the administration of oxygen therapy. The initiation of face mask supplemental oxygen delivery may be adequate; however, progressive fatigue or deteriorating respiratory status, cardiac arrest or altered conscious state warrants initiation of positive end-expiratory pressure. Non-invasive ventilation may be attempted in the alert patient. Airway management may be complicated by regurgitation of stomach contents or pulmonary oedema, thus the use of a supraglottic airway is unlikely to be effective and endotracheal intubation should be considered. Decompression of the stomach via naso- or orogastric tube should be performed only once the airway has been secured. Suctioning of ongoing pulmonary oedema post-intubation should be done with caution as this may impede ventilation and oxygenation. Aspiration of water and disruption of surfactant can impair compliance, which may interfere with rescue breaths and subsequent ventilation. Transiently, higher ventilatory peak inspiratory setting (e.g. 35 cmH$_2$O) may be required during mechanical ventilation prior to establishing open lung ventilatory strategies. Intravenous access should be obtained, and hypotension should be managed with boluses of crystalloid solution and consideration of vasoactive support. In the event of cardiac arrest, the most common underlying rhythm is PEA or asystole. Correction of hypoxaemia should be prioritised, however, if ineffective, the usual ALS algorithm should be followed. In the event of VT, consideration of alternative underlying causes should be considered including ischaemic heart disease and hypothermia. Metabolic acidosis occurs commonly and is typically managed through ventilatory compensation; routine use of sodium bicarbonate is not recommended. [17]

Hypothermia is common after a drowning event and should be managed through both passive and active warming measures; hyperthermia must be strictly avoided. [14] Resuscitation attempts should continue at least until normothermia is achieved. Seizures do not necessarily confer a poor prognosis; however, they may result in secondary brain injury and should be treated promptly. Prophylactic anti-epileptic medications are not required in the absence of seizures. Investigation of potential precipitants of, or complications resulting from the submersion event includes thorough history and examination to assess for underlying medical issues, seizures, trauma, cardiac arrest, toxicology or envenomation. Investigations should be guided by likely precipitants and may include a blood gas and blood panel, ECG and troponin, CT brain, chest x-ray, toxicology screen and echocardiogram. All patients who present with an oxygen requirement should be admitted to the hospital, those requiring ventilation (high flow, non-invasive or invasive) or who have any haemodynamic compromise should be considered for ICU admission. [17, 18]

Resuscitation of the paediatric drowning victim is similar to the adult. The main differences include standard variations of advanced paediatric life support (APLS) and an increased propensity to hypoglycaemia and hypothermia, which require early identification and management. Paediatric drownings that occur in children who are competent swimmers require evaluation for underlying medical issues (e.g. seizures or prolonged QT syndrome) and consideration of non-accidental injury. Older children and adolescents are more likely to have participated in risk-taking behaviours. [18]

Management in Intensive Care

Patients admitted to the ICU who require mechanical ventilation should be managed as per ARDS ventilation guidelines. The gas exchange typically improves quickly given the mechanism of respiratory failure, however weaning from mechanical ventilation before 24 hours is not recommended. The pulmonary injury may not have adequately resolved and liberation from positive pressure ventilation may result in the recurrence of pulmonary oedema and re-intubation. Glucocorticoid therapy has limited evidence outside the management of refractory bronchospasm. [19] Empiric antibiotic therapy is rarely indicated and may result in the selection of resistant organisms. Commencement of antibiotics should be based on the presence of fevers, laboratory markers of infection and radiographic features of pneumonia. Early pneumonia may result from aspiration of contaminated water, endogenous organisms or gastric contents. Appropriate antimicrobial therapy should be directed by local guidelines, environmental risk factors (e.g. melioidosis cover in tropical Northern Australia), drowning events in salt, fresh or contaminated water (e.g. sewerage) or positive microbiology. [20] Bronchoscopy may facilitate the identification of infectious organisms or may be helpful in the management of mucus plugs or foreign material. There is currently inadequate evidence to support the routine use of artificial pulmonary surfactant, inhaled nitric oxide and extra-corporeal life support (ECLS), however, these adjuncts may be considered on a case-by-case basis. [17] Ongoing management in the ICU includes the implementation of care to prevention of secondary brain injury. Ventilation strategies should maintain normoxia and normocapnoea, whilst ensuring an open lung ventilation approach. High PEEP should be avoided where not strictly required for hypoxaemia to reduce chances of impeded cerebral blood flow in post cardiac arrest patients. Proning and pulmonary vasodilators may be required for patients with severe ARDS and refractory hypoxaemia. Haemodynamic support should include judicious fluid replacement and potentially vasopressor support to maintain normotension. A conservative fluid approach may improve lung function and shorten the duration of mechanical ventilation. Clinically evident and EEG-proven non-convulsive seizures should be treated. Normoglycemia should be maintained and electrolyte disturbances addressed. [21] A tertiary survey should be considered when appropriate.

Prognostication

Prognostication of those referred to the ICU remains difficult. Evolution of pre-hospital and hospital care makes it difficult to translate earlier studies investigating predictors of outcomes following drowning events. Studies evaluating drowning outcomes are limited to cohort, case series and case-control studies. [22] Prognostication and evaluation of the research are further compounded by published individual cases where survival with good neurological outcomes has been achieved despite prolonged submersion. Furthermore, long-held views, such as outcomes being more favourable when the drowning occurs in cold water, have not been consistently demonstrated.

Predictors of Outcome

The most recent published meta-analysis exploring factors that may predict outcomes was completed in 2016 and commented on several prognostic factors. [23] The authors emphasise the low quality of evidence available, however, identified an emergency response time of less than 9 minutes, shorter submersion times and saltwater immersion as being favourable.

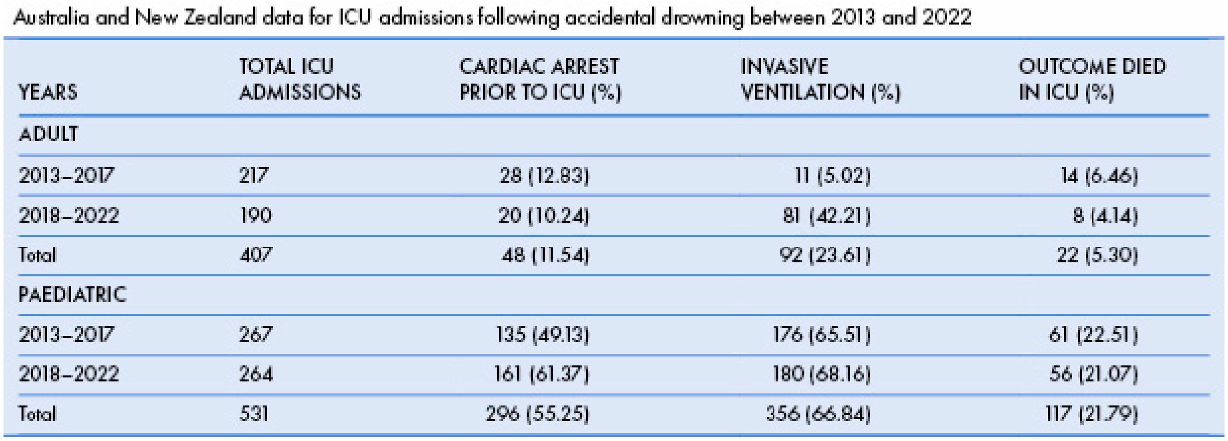
In retrospective studies, the most consistently demonstrated predictor of outcome is the duration of submersion regardless of adult or child. A review of retrospective studies found that a submersion duration of <5 minutes conferred a 10% risk of mortality or severe neurological impairment after hospital discharge. Beyond 5 minutes, this risk rose significantly to 56% at 5–10 minutes, 88% at 11–25 minutes and 100% at >25 minutes. [24-29] Prognostication in the time interval between 5 and 25 minutes is difficult with survival rates described between 12% and 45%.

Despite reports of individuals surviving prolonged cardiac arrests following submersion in icy water, there is no evidence that drowning in cold water predicts improved survival. Water temperature has been examined in individual studies with authors concluding that a water temperature <6°C can be protective and permit longer periods of submersion with a neurologically intact survival however others have failed to reproduce that. [18] In Australia and New Zealand, hypothermia is likely to reflect a prolonged duration of submersion which is linked to poor prognosis. [14] Some authors suggest that the increased saltwater survival may be explained by an increased prevalence of psychiatric disorders and suicide attempts in the freshwater cohort. Psychiatric disorders with a suicide attempt, as well as drowning with drug and alcohol ingestion, have been identified as factors which have a higher mortality. [30]

In terms of clinical prognostication, arrival to the hospital with a beating heart is a strong determinant of survival and increases the chance of surviving neurologically intact. [31] The mortality associated with drowning complicated by cardiac arrest is 90% compared with respiratory arrest alone which is 30%–45%. Other strong predictors of mortality include age <3 years and >14 years, any delay in resuscitation or response time, a GCS less than 5 on arrival to the hospital and an arterial pH <7.1. [32] Specifically in the paediatric population, a lactate >14 mmol/L, a blood glucose level >15 mmol/L and a core body temperature <30°C are all features that are associated with a poor neurological outcome or death. [33]

Survival from a drowning event varies greatly. Overall, the trend to survival is improving, which may in part be secondary to advances in the understanding and management of cardiac arrest. Table 102.1 summarises the ANZICS data for ICU admissions related to drowning over the past decade. [34]

Table 102.1



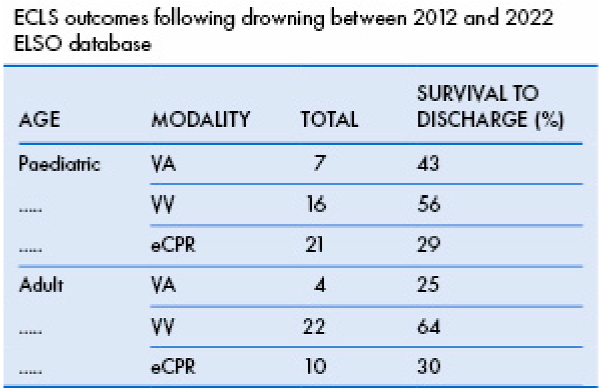
Australia and New Zealand data for ICU admissions following accidental drowning between 2013 and 2022

YEARS	TOTAL ICU ADMISSIONS	CARDIAC ARREST PRIOR TO ICU (%)	INVASIVE VENTILATION (%)	OUTCOME DIED IN ICU (%)
ADULT				
2013–2017	217	28 (12.83)	11 (5.02)	14 (6.46)
2018–2022	190	20 (10.24)	81 (42.21)	8 (4.14)
Total	407	48 (11.54)	92 (23.61)	22 (5.30)
PAEDIATRIC				
2013–2017	267	135 (49.13)	176 (65.51)	61 (22.51)
2018–2022	264	161 (61.37)	180 (68.16)	56 (21.07)
Total	531	296 (55.25)	356 (66.84)	117 (21.79)

Long-term outcomes for patients who survive ICU are largely unknown. One case series of paediatric patients demonstrated a range of outcomes including death in the ICU, death within 6 months, requirement for long-term care in a healthcare facility and discharge home. Of the survivors, follow-up included an assessment of long-term health-related quality of life (HRQoL). This found that older age at the time of the event and the longer the submersion time were associated with a reduction in HRQoL. [35]

Data around short and long-term outcomes for patients placed on ECLS is limited. Table 102.2 demonstrates data extracted from the ELSO database for adult and paediatric patients placed on either VA or VV ECMO between 2012 and 2022. [36]

Table 102.2



ECLS outcomes following drowning between 2012 and 2022 ELSO database

AGE	MODALITY	TOTAL	SURVIVAL TO DISCHARGE (%)
Paediatric	VA	7	43
.....	VV	16	56
.....	eCPR	21	29
Adult	VA	4	25
.....	VV	22	64
.....	eCPR	10	30

Treatment decisions regarding patients who have experienced drowning events should be made on a case-by-case basis. Aggressive initial resuscitation and ongoing ICU support are justified given evidence that a small number of cases will not only survive but will do so neurologically intact. This should be revised when more history is obtained and a response or lack of response to treatment is observed. This is particularly the case for the paediatric population. Although there is no exact method for predicting mortality, knowledge of these factors and their potential associations with outcomes will help the treating intensivist counsel families and help decide on the appropriateness of escalating therapies. Depending on local policy, a patient who has reached medical futility could be considered for organ donation. Australian data from 2012 to 2022 show an average of 9 donors per year from drowning deaths. [37]

Research in Drowning

To date, there have been no randomised control trials investigating the key areas of drowning management, including resuscitation, airway management, oxygen administration, the use of automated external defibrillators, CPR, ventilation strategies, ECLS and protocols for hospital discharge. Retrospective data on outcomes and factors contributing to outcomes is important for continuing to improve the management of and outcomes related to drowning events. The Utstein guidelines are an established consensus guideline, endorsed by ILCOR for uniform reporting of data from drowning-related resuscitation. [38]

Burns

Edward John Richard Watson and Marcela Paola Vizcaychipi

Abbreviations

ACS	Abdominal compartment syndrome
ARDS	Acute respiratory distress syndrome
ALS	Advanced life support
ATLS	Advanced trauma life support
CO	Carbon monoxide
CPOT	Critical Care Pain Observation Tool
ICU	Intensive care unit
ICU-AW	ICU-acquired weakness
MODS	Multiple organ dysfunction syndrome
TBSA	Total body surface area
TENS	Toxic epidermal necrolysis syndrome
WHO	World Health Organisation

Introduction

Severe burn injuries requiring admission to the intensive care unit (ICU) comprise a unique cohort of patients that present with substantial heterogeneity. The injuries encountered can be as broad in nature as scalds, electrical contact, radiation, and chemical exposure. The patients vary from children reaching for hot pans, epileptics falling against radiators, nursing home residents smoking in bed, house fires, the inebriated falling from railway platforms, bleach assaults and self-immolation injuries.

They are, however, united in their initial presentation to the hospital as instances of instant and enormous cutaneous injuries with overwhelming inflammatory dysregulation. This requires specialist input from multidisciplinary teams familiar with the trajectory and care requirements that inevitably ensue. This chapter will discuss the management of patients from the point of admission to hospital.

Since the advent of critical care units and organ support, and even despite a dearth of high-quality evidence,[1] survival from major burns continues to improve.[2,3] In lieu of serious underlying comorbidity, patients can expect to survive seemingly catastrophic burns. There are no limitations to care based on total body surface area (TBSA) alone.

These improvements in survival have led to a recent shift of emphasis in burn care towards qualitative aspects such as rehabilitation, psychological support and quality of life.

Centralisation of Care

Alongside clinical advances, the most important development in survival has been the establishment of centralised burn care. The multidisciplinary burn team comprises specialist surgical and critical care teams, anaesthetists, dieticians, physiotherapists, pharmacists and psychologists. Specialist facilities provide temperature-controlled rooms, isolation facilities and access to large quantities of specialist dressings.

The incidence of major burns is now very low, requiring the organisation of services on a national level to cluster knowledge and experience. However, due to the low number of beds per capita, a mass casualty incident can overwhelm standard local provision. As such, the burns community is configured to redistribute patients rapidly across internal and international borders.

Spectrum of Disease

The World Health Organisation (WHO) defines a burn as ‘an injury to the skin or other organic tissue primarily caused by heat or due to radiation, radioactivity, electricity, friction or contact with chemicals’. [4]

Typically, they primarily involve cutaneous exposure requiring input from the specialist surgical team. There is a focus on debriding dead tissue and reconstituting the natural barrier – initially through dressings, progressing to grafting. However, burns can also be internal, for example, bleach ingestion, radiation and inhalational burns.

Depending on the organisation of services, non-cutaneous burns may be cared for in a general ICU. However, other diseases such as toxic epidermal necrolysis syndrome (TENS) may be cared for in a burns unit.

Even within each mechanism of injury, there are important subcategories to bear in mind that affect management. For example, scalds are more likely to cause deep tissue damage than flash burns but less likely to be associated with traumatic or inhalational injuries. Caustic solutions cause deep saponification, typically requiring more extensive debridement than those that do not.

Spectrum of Patients

Burns can affect any member of society at any age. However, truly accidental burns are less common now due to advances in health and safety. There is an early peak in paediatric scalds at an age when children can reach kitchen surfaces. There is a high representation of substance misuse patients smoking in bed while inebriated and of self-immolation injuries in patients with psychiatric disease. Others present as victims of assault with bleach, or arson through the use of accelerants. The history gained from witnesses and emergency services is critical in establishing exactly what happened; be vigilant for red flags suggestive of associated injuries.

Pathophysiology

Paradigm of ‘The Severe Burn’

Local Effects

As with any injury, a local inflammatory response results in vasodilatation and increased vascular permeability. Microthrombus formation, neutrophil adherence, fibrin deposition and endothelial swelling occur within minutes to hours.[5,6]

Severe burns involve large surface areas, and the extravasation of fluid and plasma proteins results in marked oedema formation.[6] This warm, nutrient-rich tissue fluid serves as a petri dish for colonising organisms such as pseudomonas.[7] Mass evaporation of water leads to hypothermia. Rapid and considerable third-spacing of fluids causes intravascular hypovolaemia, which if left untreated will cause systemic shock.

However, over-zealous fluid administration will exacerbate tissue oedema. On a microvascular level, this contributes to the enlargement and deepening of the burn area penumbra through hypoperfusion.[6,8,9] At a macrovascular level, oedema with circumferential burns can result in compartment syndrome.[10]

Inhalational injury represents a combination of thermal injury to the epithelium, inhalation of toxic gases, and obstruction from inhaled detritus, oedema, sloughing epithelial casts and clots.[11]

Systemic Effects

There are varying definitions of a ‘major’ burn, expressed in terms of TBSA, ranging from above 10%–30%. TBSA as a sole variable has limitations: it does not account for burn depth, mechanism of injury, or concomitant injuries. However, most would agree that a hallmark of a severe burn is the development of systemic features such as inflammatory dysregulation and hypermetabolism. In 1942, Cuthbertson coined the term ‘ebb and flow’ which has since characterised the physiological response to major burns.[12]

The ‘ebb’ phase represents an early reduction in cardiac output from a combination of hypovolaemia, increased blood viscosity, and secretion of chemical mediators with myocardial depressant properties (e.g. interleukin-1 and TNF-α).[13] Endogenous epinephrine, norepinephrine, vasopressin and angiotensin cause an increase in systemic and pulmonary vascular resistance.[14] This, coupled with inflammatory-mediated capillary leak, predisposes to pulmonary oedema.

By day three patients enter a catecholamine-driven ‘flow’ phase. This manifests with extremely high cardiac output and hypermetabolism[13] characterised by amplified resting energy expenditure, skeletal muscle catabolism, insulin resistance and hyperthermia. These metabolic changes will taper but can last for years after injury.[13]

Burns patients are also at risk of acute kidney injury from a combination of hypovolaemia, inflammation, rhabdomyolysis, nephrotoxic agents, and abdominal compartment syndrome (ACS).[8], [15] Other features of multi-organ dysfunction syndrome such as immunoparesis, transaminitis, anaemia and delirium invariably follow.

Notable pharmacokinetic and pharmacodynamic changes occur after burns.[16-18] The circulatory changes in the ebb and flow phase impact drug distribution, gross oedema increases the volume of distribution, and hypoproteinaemia reduces drug binding. The hypermetabolic state can increase the metabolism of some drugs, though renal and hepatic dysfunction will reduce the clearance of others.[16] Drugs can be lost directly through the burn exudate. Guidance from specialist pharmacists and drug-level monitoring, when available, can help steer therapy.

Assessment

A careful history and examination should be performed according to the Advanced Life Support (ALS)[19] or Advanced Trauma Life Support (ATLS)[20] algorithm, as appropriate to the mechanism of injury. Major burns patients should be referred to a burns centre for transfer and admission, facilitated by telemedicine for early specialist assessment and advice.[21]

Airway and Breathing

Upper airway burns result from inhalation of hot gasses and can lead to obstruction through laryngeal oedema. This will be progressive over the course of several hours. Flash burns may cause marked external facial and lip burns with singed nostril hair. However, due to the transient nature of exposure, they are much less likely to cause airway inflammation and obstruction.

Face and neck injuries should not be routinely intubated. [21] However, a history of prolonged exposure to hot gasses, such as a fire in an enclosed space or ignition of clothing, are cause for concern. Pharyngeal erythema, voice changes, breathlessness, carbonaceous secretions, circumferential neck burns and reduced level of consciousness are all red flag features that should trigger a decision regarding intubation. This should be contextualised: a full facial burn in and of itself may not require intubation, but if associated with a large TBSA injury, the anticipated fluid and oedema burden may warrant airway protection. [21]

Fibreoptic examination of the larynx can be a useful adjunct for decisions regarding intubation. [22] Bronchoscopy can be performed to grade the level of lung injury, but should not delay transfer. [23]

For any inhalational injury, consider the risk of carbon monoxide (CO) and/or cyanide inhalation. Other inhaled chemicals may be produced in industrial accidents or bleach-related burns. [24]

Carbon monoxide is produced in any fire where hypoxic conditions exist. It binds to haemoglobin with 236 times the affinity of oxygen, [25] as well as to myoglobin [26] and intracellular cytochrome systems. [27] Death is increasingly likely at carboxyhemoglobin concentrations above 60%. [24]

Hydrogen cyanide is produced from the combustion of synthetic materials. It blocks electron transfer from cytochrome oxidase to oxygen. [28] Neurological and cardiovascular symptoms can start within seconds of exposure and are rapidly fatal.

Circulation

Systemic sequelae of major burns are characterised by classic signs of hypovolaemia: cool peripheries, weak pulse volume, prolonged capillary refill time, reduced urine output and lactic acidosis. A high lactate coupled with cardiac ischaemia on ECG monitoring should prompt consideration of treatment for cyanide poisoning. [28]

Look specifically for circumferential wounds to the neck, chest, trunk and limbs. Assess for distal limb perfusion, though compartment syndrome usually presents later following the development of significant oedema.[10]

ECG stickers may need to be stapled on in areas devoid of skin. Invasive monitoring such as arterial and central lines can be placed through injured tissue if necessary. Occlusive dressings will not adhere to burnt flesh and iodine-soaked gauze can be used instead. Deeper sutures may be required to tether lines due to lack of skin integrity.

Disability

Pain should be assessed and treated with adequate analgesia promptly.

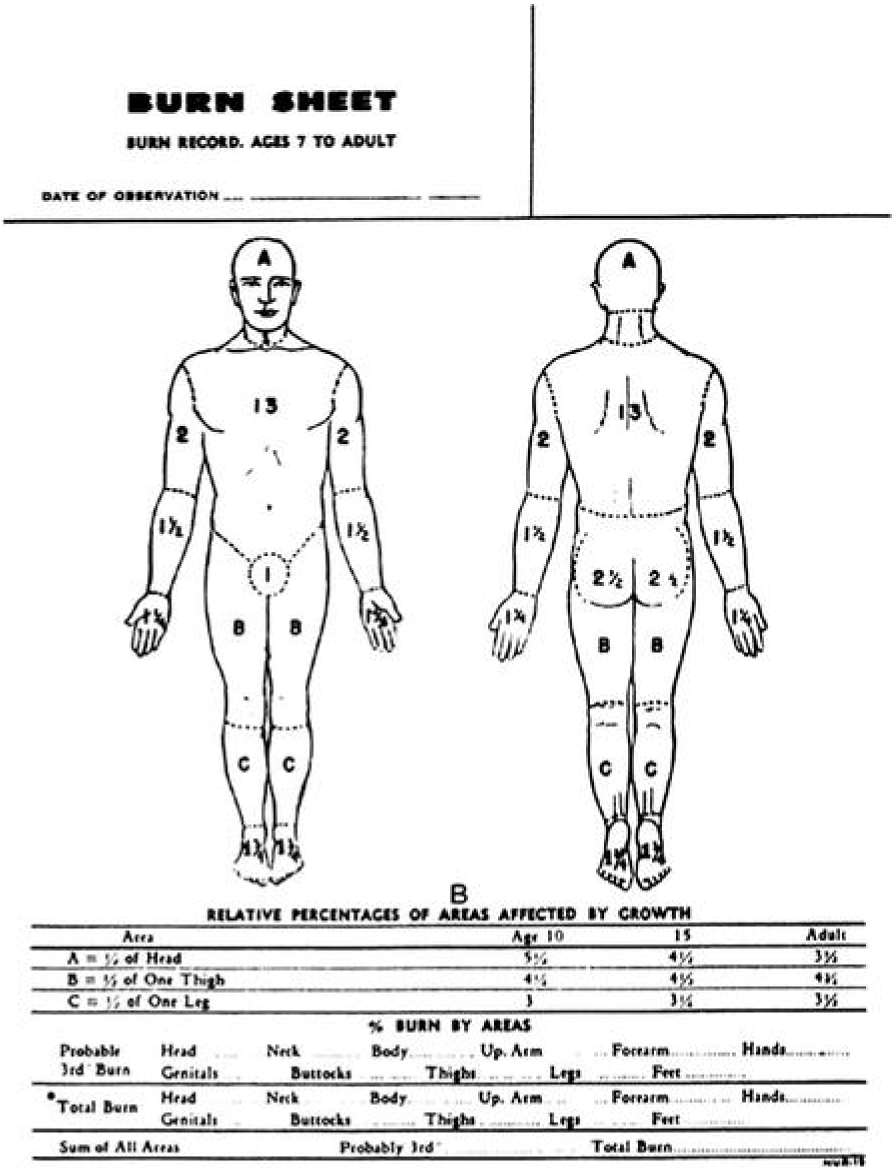
Reduction in conscious level in burns can be cause or effect. Any condition that results in reduced conscious level can lead to an accidental burn, with common examples being alcohol and drug excess, hyper/hypoglycaemia and epilepsy. Suicide attempts and psychotic episodes may involve an intentional drug overdose and a toxin screen should be considered. Inhalation of hypoxic air and/or toxic gases such as carbon monoxide, carbon dioxide and cyanide compounds can cause a reduction in conscious level. All these can also result in a head injury.

Exposure

A full head-to-toe examination must be performed. Avoid exposing the patient for any longer than necessary to avoid fluid and heat losses. Cling film can be used on initial presentation as a readily available barrier.

Cutaneous injury should be assessed not only by TBSA but also by the depth of burn and areas affected. Specific note should be made of circumferential burns, and any burns to hands, feet, face, perineum or genitalia. For electrical burns, both entry and exit wounds should be identified.

Estimation of burn size can be facilitated by Lund and Browder charts[21], [29] (Fig. 103.1) or the ‘Rule of Nines’[30] (Fig. 103.2). The Rule of Nines is modified for children (Fig. 103.3). Burn depth can be described either as superficial to deep or first to fourth degree. Imaging should be transferred to a burns centre, as burn size is frequently modified when estimated by an experienced surgeon.



BURN SHEET

BURN RECORD. AGES 7 TO ADULT

DATE OF OBSERVATION ____________

B

RELATIVE PERCENTAGES OF AREAS AFFECTED BY GROWTH

Area	Age 10	15	Adult
A = ½ of Head	5½	4½	3½
B = ½ of One Thigh	4¼	4½	4¾
C = ½ of One Leg	3	3¼	3½

% BURN BY AREAS

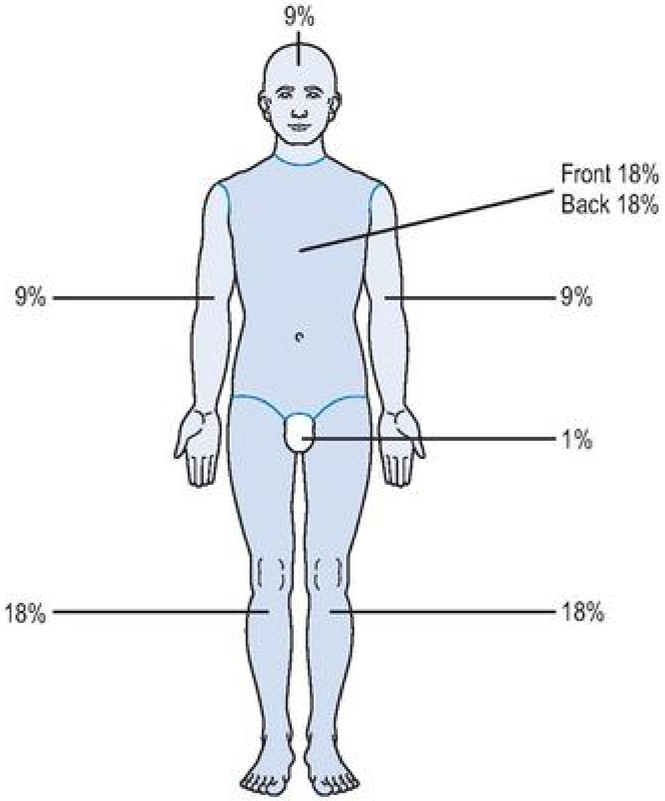
Probable 3rd° Burn: Head ...... Neck ...... Body ...... Up. Arm ...... Forearm ...... Hands ...... Genitals ...... Buttocks ...... Thighs ...... Legs ...... Feet ......

*Total Burn: Head ...... Neck ...... Body ...... Up. Arm ...... Forearm ...... Hands ...... Genitals ...... Buttocks ...... Thighs ...... Legs ...... Feet ......

Sum of All Areas Probably 3rd° ...... Total Burn ......

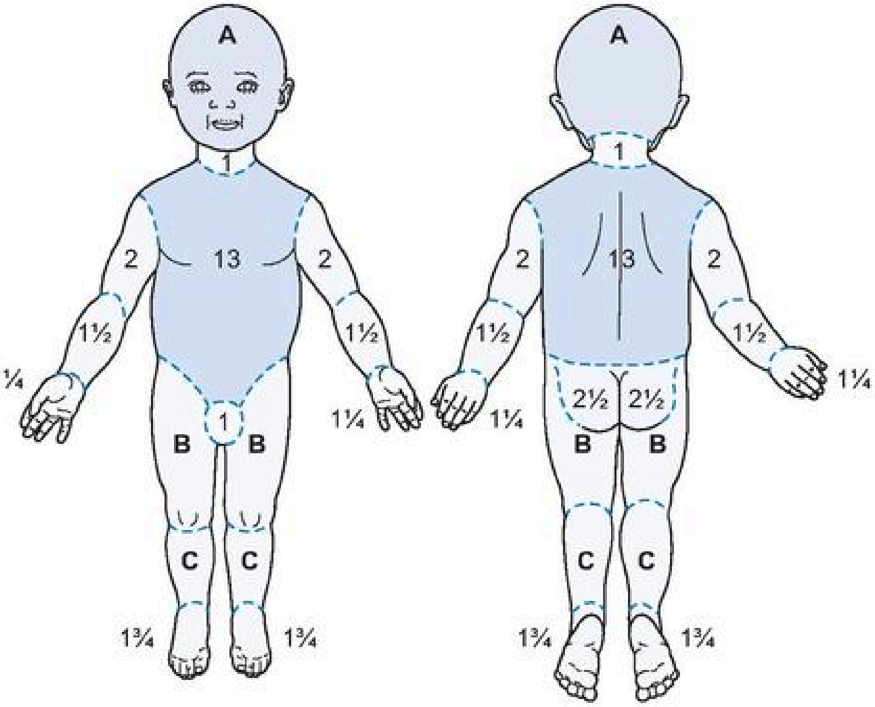
The medical chart titled Burn Sheet is designed to record burn details for ages 7 to adult. It features two human outlines, a frontal and a rear view. Each section of the body is labelled with numbers representing burn percentages related to specific body areas. The frontal view includes numerical values on the head, torso, arms, legs, and genital area. The rear view similarly labels body sections. Below the illustrations, a chart outlines relative percentages of body areas affected by growth, comparing age groups including 10, 15, and adult. There is also a table titled Percent Burn by Areas for detailed record keeping of burn percentages across different body parts.

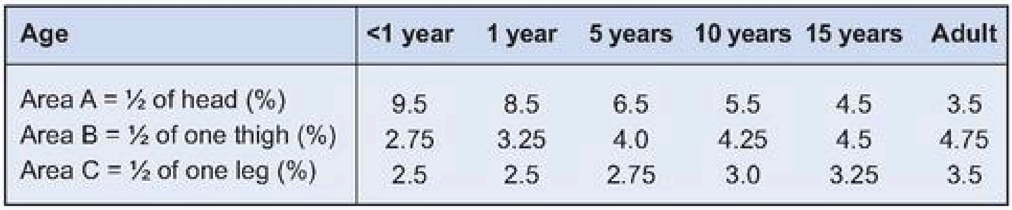
FIG. 103.1 Lund and Browder chart for estimation of TBSA in adults. (From Sabeston DC Jr, ed. *Textbook of Surgery: The Biographical Basis of Modern Surgical Practice* , 11th ed. Philadelphia: Saunders; 1977.)



The illustration of a human figure shows sections of the body marked with percentages. These percentages represent the body surface area used in medical assessments. The figure is presented in a front-facing position. The head is marked with 9 percent, each arm is labelled 9 percent, the torso has labels indicating front 18 percent and back 18 percent, the genital area is marked 1 percent, and each leg is labelled 18 percent.

FIG. 103.2 The Rule of Nine to estimate TBSA in adults.





Age	<1 year	1 year	5 years	10 years	15 years	Adult
Area A = ½ of head (%)	9.5	8.5	6.5	5.5	4.5	3.5
Area B = ½ of one thigh (%)	2.75	3.25	4.0	4.25	4.5	4.75
Area C = ½ of one leg (%)	2.5	2.5	2.75	3.0	3.25	3.5

The illustration shows a child from frontal and rear views, sectioned into various outlined areas. The body is marked with areas labelled A, B, and C over the head, thighs, and legs, respectively. Each area is associated with specific percentage values, indicating proportions related to body surface area. The frontal view has a shaded area labelled 13 covering the chest and abdomen, extending to the arms. The posterior view mirrors similar marking conventions. Below the illustration is a table titled Age listing percentages for areas A, B, and C across different age groups, including less than 1 year, 1 year, 5 years, 10 years, 15 years, and adult. The percentages decrease with age.

FIG. 103.3 The Rule of Nine to estimate TBSA in children.

Rhabdomyolysis presents with a classic triad of myalgia, muscle weakness and tea-coloured urine. At a later stage in sedated patients, only the urine changes may be observed.

Mortality Estimation

The revised Baux score is the sum of the patient's age, TBSA and an additional 17 points if an inhalation injury is present. It can be used for an estimate of mortality, with a median lethal dose (LD_{50}) of 113.[31]

Management

Burns resulting from neglect or abuse in vulnerable groups are safeguarding issues which require appropriate follow-up by relevant authorities. Always consider non-accidental injury in children.

Airway

If a traumatic mechanism is suspected, use an ATLS approach and consider cervical spine protection.[20]

Intubation, if required, is best performed early before laryngeal oedema develops. The use of high-flow nasal oxygen is useful for intubation, particularly if facial injuries preclude a good mask fit.[32]

Depolarising neuromuscular blockers are safe to use on first presentation, but after 24–48 hours they can precipitate life-threatening hyperkalaemia due to up-regulation of extra-junctional acetylcholine receptors.[33]

The widest endotracheal tube feasible should be inserted, as repeat bronchoscopies will likely be necessary. Do not cut the tube, as the end will be lost to facial oedema in the next few days. For the same reasons, securing the tube is important: repeat intubation will be extremely difficult. A standard tube tie can be used initially, but this will have to be loosened progressively. Under certain circumstances, the tube may need to be secured by means of a suture through the gums or around a tooth.

Expect thick carbonaceous secretions, have suction immediately available and be prepared to perform bronchoscopy for diagnosis and lavage.

Patients are nursed without a pillow to avoid a fixed flexion deformity from contractures. [34]

Breathing

Regular bronchoscopy, chest physiotherapy and nebulised saline, N acetylcysteine (NAC), heparin and bronchodilators help to clear the lower airways. [35] If a circumferential chest wound is present, this should be released with escharotomies. [10]

If carbon monoxide poisoning is demonstrated on blood gas analysis, administer high-concentration oxygen. The half-life of carboxyhaemoglobin is 320 minutes when breathing air, [36] compared to 75 minutes with 100% oxygen. [37] In severe CO poisoning consider discussion with a hyperbaric centre to reduce the risk of long-term cognitive impairment. [24] However, the care requirements of a burn injury likely preclude this therapy.

Hydroxycobalamin should not be given routinely for inhalational injuries. [21] However, if cyanide poisoning is suspected, it is the preferred antidote and should be administrated within two hours. [38]

Burns patients are especially prone to acute respiratory distress syndrome (ARDS). Standard lung protective ventilatory strategies should be used. Ventilator-associated pneumonias are also common due to prolonged ventilation, copious pooling of airway secretions and heavy colonisation from surrounding wound beds. [39]

Circulation

Burns patients can demand extraordinary volumes of fluid to replace wound losses. The last half century has been dominated by a paradigm of formulaic fluid prescriptions, the most notable being the Parkland formula. [40] This pushed for higher replacement rates than were common at the time, but many validation studies have since demonstrated that it still tends towards under-resuscitation. [41]

It recommends that 4 mL crystalloid solution is administered in the first 24 hours, per TBSA, per kilogram of body weight (3 mL in children). This is front-loaded: half is given in the first eight hours and the other half in the subsequent sixteen hours. [40]

The Parkland formula remains a useful baseline for fluid administration guided by easily obtainable variables, but there are other important factors. Patients with deeper burns, inhalational injuries, and long exposures require more fluid. There may also be other reasons for dehydration at baseline, such as intoxication, exertion, medical comorbidity and season.

Maintenance of intravascular volume is critical to avoiding a shock state. [42] However, if too much fluid is administered then organ perfusion will be hampered by tissue oedema, pulmonary oedema and ACS. More recent consensus statements warn against the risk of over-zealous fluid administration. [43], [44] Resuscitation should be with a balanced crystalloid solution in the first instance, with human albumin solution used as an adjunct after the first 6 hours if >30% TBSA. [21]

The excessive use of vasopressors to offset fluid intake is also perilous for organ perfusion. Initial resuscitation is primarily with isotonic crystalloid. [42] Albumin is often used as an adjunct and may be associated with reduced risk of excessive fluid therapy (fluid creep), [45] ACS and mortality. [46] Invariably, burns patients shift towards a paradoxical state of gross systemic oedema while intravascularly deplete.

Urine output is the standard endpoint for resuscitation, [47] with 0.5–1 mL/kg/h in adults and 1–2 mL/kg/h in children being common targets. This is contextualised by clinical examination and other standard parameters such as cardiac output monitoring, [48] base deficit and lactaemia. [21]

Neurology

Pain and delirium are inherent complications of major burn injuries, good management is central to later rehabilitation.[49] Acute pain is associated with an exacerbated stress response, generates anxiety and contributes to post-traumatic stress.[50]

In intubated patients, scoring systems such as the Critical Care Pain Observation Tool (CPOT) can be used to assess pain and optimise analgesia.[51,52] Pain can be caused by the burn itself, dressing changes, debridement, skin donor sites, positioning and physiotherapy, and invasive procedures. In addition to pain, patients describe other distressing symptoms related to their wounds such as dysthaesia, paraesthesia, numbness, pruritis and diaphoresis.

In severe burns requiring intubation, pain is initially managed with high-dose infusions of opioids. Gradually, these infusions are converted to slow-release enteral preparations.

The principles of multimodal analgesia should apply throughout.[21] Regular paracetamol should be used so long as liver function permits. Nonsteroidals are usually contraindicated during the acute critical care period due to the risk of acute kidney injury, wound bleeding and peptic ulceration. Gabapentin is useful for neuropathic pain and pruritis, both common in burns.[53] A-2-agonist are effective analgesics that also help with delirium[54] and modulation of the hypermetabolic state.

Down-regulation of opioid receptors presents a problem for procedural and operative pain. Ketamine is a useful adjunct,[21] and volatile anaesthetics are emerging as an alternative to high-dose opioids. Patient-controlled analgesia pumps can be effective, though may be limited by hand dressings and delirium. Use non-pharmacological adjuncts when possible, and titrate treatments to validated pain-scoring systems.[21]

Examination of the eye with fluoresceine dye should be performed early to reveal any corneal injury.[55] Regular care of ophthalmological burns involves the immediate decontamination of the eyes with isotonic solution, as well as the subsequent regular application of artificial tears and antibiotic ointment. Tape and dressings may need to be applied in the management of lagophthalmos.[56] Amniotic membrane transplantation is no longer thought to provide any benefit for ocular burns.[57]

Renal

Over a third of burns, ICU patients will suffer an AKI, and one in eight will require renal replacement therapy. [58]

Given the extreme levels of oedema encountered, vigilance is required for ACS. Vesicular compartment pressures should be monitored regularly. [8] Circumferential abdominal burns should undergo escharotomies. [10]

Rhabdomyolysis is common in deep burns. Myoglobin and haemoglobin release from damaged muscle and blood cells cause obstructive nephropathy. The hallmark sign is a discolouration of the urine, from faint pink to dark black, accompanied by a rise in serum creatine kinase levels. Polyuria from increased fluid administration and urine alkalinisation are commonly advocated strategies, though they have a poor evidence base. [59]

Haematology

Major burns patients incur frequent surgical procedures, requiring repeat transfusions. A higher baseline haemoglobin of 100 g/L is targeted due to the risk of massive haemorrhage. Prior to any surgical procedure, ensure coagulopathy is treated and adequate quantities of blood products are available. Operating time is limited by hypothermia; a high-normal baseline temperature can allow more thorough initial debridement before becoming coagulopathic.

Prevention of venous thromboembolism is problematic. Burns patients are at high risk of thromboembolism due to immobility, systemic inflammation, high-viscosity blood and endothelial dysfunction. [60] Leg burns preclude mechanical thromboprophylaxis. Pharmacokinetic challenges can be ameliorated by APTTR and anti-factor Xa assays, but a combination of surgery, bleeding and coagulopathy still causes frequent interruptions in heparin administration.

Nutrition and Metabolism

Burns patients experience unparalleled catabolic states, with energy expenditure in proportion to the size of the burn. [13] Additionally, they lose fluid, protein, electrolytes and trace elements through wound exudate.[61,62]

The gold standard for calculating calorific requirements is indirect calorimetry. When unavailable, the Toronto[63] (adults) and Schofield[64] (children) equations can be used. Higher levels of protein are recommended (1.5–2 g/kg in adults, 3 g/kg in children).[65] Trace elements levels (selenium, zinc, manganese and copper)[65] and vitamin D[66] should be monitored and routinely supplemented. Glutamine is no longer recommended.[67]

Early enteral nutrition using post-pyloric feeding is preferable.[65] Ideally, initiation of enteral nutrition should be within eight hours of admission to ICU to potentially attenuate the hypermetabolic and stress response[68] and reduce the incidence of stress ulcers.[65] Ileus is common, therefore administration of regular laxatives is recommended, with prokinetics when indicated.

Further catabolic attenuation can be achieved with continuous insulin infusions and propranolol,[65] but due diligence is required for the risk of hypoglycaemia and bradycardias respectively. The use of testosterone analogues such as oxandrolone is well established in major burns.[65] Non-pharmacological methods include early debridement and thermo-neutral rooms.[65]

Transaminitis is common in burns patients due to the combination of multiple organ dysfunction syndrome (MODS) and hepatotoxic therapies such as parenteral nutrition and antimicrobials.

Microbiology and Immunology

Sepsis remains the most common cause of death in burns.[7,69,70] In practice, it is extremely difficult to differentiate sepsis from the expected trajectory of systemic inflammation. Aseptic burns patients will be flagged as septic when using conventional markers or diagnostic criteria. Constitutional changes such as large gastric aspirates, ileus, increasing insulin resistance and worsening pyrexia offer clues towards a diagnosis of sepsis.[70] Procalcitonin has been shown to have some value as a diagnostic discriminator, but its use requires contextualisation.[70,71]

Routine surveillance cultures are useful to detect the inevitable colonisation with multi-resistant organisms and guide antimicrobial therapy.[7] Routine use of prophylactic antimicrobials is not recommended.[21] The use of isolation rooms and barrier nursing is obligatory.

Surgery

The focus of surgical management in early burns is threefold: to perform any necessary escharotomies and prevent compartment syndrome of the neck, chest, abdomen, limbs and digits[10]; to debride dead tissue and reduce the inflammatory and metabolic insult; and to apply allograft tissue to return the protective functions of the skin. Unlike crush injuries, the onset of compartment syndrome in burns tends to be delayed, after oedema has had time to develop. Escharotomies should ideally be performed by an expert after transfer to a burns centre.[21]

Early excision and grafting of burns have been shown to improve survival, and should ideally be completed within the first week,[72] before bacterial colonisation and neovascular infiltration of the wound bed develop.

Autografting is avoided early on when the chances of losing a graft from hypoperfusion, oedema or infection are high. Ideally, a one-to-one graft is performed, but in larger surface area burns this may be one-to-three or one-to-nine. In extremis, skin cells from small surviving patches of skin can be cultured and sprayed onto the rest of the body.[73]

Later plastic surgical management focuses on function and aesthetics. Other specialty teams may need to be involved for tracheostomy insertion, and for ophthalmological and urological input.

Follow-Up

Burns survivors experience all the common complications of critical care, including ICU-acquired weakness (ICU-AW), dysphagia, dysgeusia, sexual dysfunction, incontinence, neurocognitive impairment, depression, anxiety and post-traumatic stress.[74] However, in addition to ICU-AW, function in burns patients can also be limited by sensory loss (tactile, visual and auditory), contractures and amputations.

In addition to the critical care admission, many burn patients also endured an extremely distressing event at the time of injury. Many suffered from psychiatric illness beforehand, which may have caused the burn. Visible scarring will impact interactions with new people. Severe burns patients can face years of repeat surgical procedures, exacerbating psychological symptoms.

In addition to their psychological burden, care for patients returning for repeat procedures should be mindful of ongoing physical deconditioning, hypermetabolism [13] and opioid tolerance. [75] They may have complications such as tracheal stenosis, [76] blood antibodies and multi-resistant organisms. [7]

Thermal disorders

Stephen William Lam, Lisa-Marie Pereira and Richard Strickland

Normal Temperature Regulation

Humans are endotherms and can maintain a remarkably constant core body temperature (T_c) across a wide ambient temperature range.[1-3]

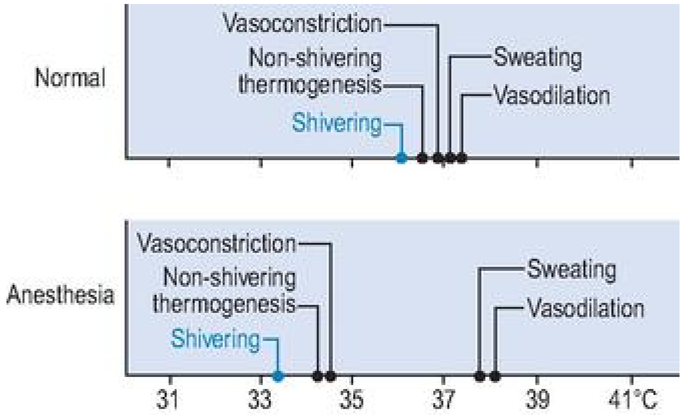
Heat production may be obligatory or facultative. Obligatory production is continuous, arising from processes essential for cell survival including basal metabolic rate and dynamic action of food. Facultative production is intermittent, arising from thermogenesis in brown adipose tissue and skeletal muscle activity. Heat is gained from the environment if the environmental temperature exceeds the mean skin temperature, generally when the ambient temperature exceeds 35°C. Heat is lost by radiation, conduction, convection and vaporisation from sweat and the respiratory tract, which can be limited by high ambient temperature or humidity. A very small amount of heat is lost in urine and stool.[1,2]

The body has two conceptual thermal compartments, an outer shell comprising the skin and subcutaneous fat, and an inner core. The shell provides feed-forward signals that allow the body to respond to thermal loads.[1-5] Current models of thermoregulation suggest core temperature (T_c) is maintained in an interthreshold zone or ‘balance point’ by a series of thermo-effector loops.[1,2] Whilst central reciprocal cross inhibition of thermo-effector loops occurs, the concept of a centrally regulated set point has been replaced.[1-3]

Temperature sensing occurs in the skin, deep tissues and centrally, providing afferent input to thermo-effector loops.[1-5] In the dermis and epidermis, temperature-activated transient receptor potential (thermo-TRP) ion channels are cold or heat-activated at differing thresholds.[6] Input from these channels travels via the dorsal root ganglion to the brainstem, where fibres for warm-sensitive neurons project to the preoptic anterior hypothalamus, and cold-sensitive neurons to the posterior hypothalamus.[1,2,4] Similar afferent inputs are derived from deep thoraco-abdominal musculature, large vessels and many organs. In the brain, input comes from thermosensitive neurons in the preoptic anterior hypothalamus, circumventricular organs (capillary networks surrounding hypothalamic temperature regulation centres), midbrain and spinal cord.[1,2,7]

When thermo-afferent input reaches threshold, thermo-effector loops are stimulated with a resultant heat loss or heat gain response via behavioural, autonomic or endocrine mechanisms.[7,8] Behavioural responses, which appear to be driven predominantly by peripheral input, are generally more energy efficient, afford the greatest degree of thermoregulation and often pre-empt significant changes in T_c. If behavioural responses are inadequate there is recruitment of autonomic regulation.[1,2]

Autonomic responses are characterised by a threshold, gain and maximal response (Fig. 104.1). T_c above 37°C results in cutaneous vasodilatation and sweating mediated predominantly by cholinergics.[7] When accompanied by an appropriate increase in cardiac output (≈3 L/min/°C, up to a maximum of around 13L/min), vasodilation results in core-to-cutaneous heat transfer. Skin blood flow may increase from a basal rate of 0.2 L/min up to 8 L/min at T_c ≈39.0°C with diversion of blood volume and flow away from core compartments and organs such as gut and kidneys.[9] However, reflexes maintaining blood volume and pressure take precedence over thermoregulation; diminished ability to increase cardiac output limits vasodilatory heat loss, and dehydration reduces sweating capacity.[8,10]



The chart exhibits thermoregulatory response thresholds labelled Normal and Anaesthesia across a horizontal axis ranging from 31 to 41 degrees Celsius. Each panel marks thresholds for five responses, namely vasoconstriction, non-shivering thermogenesis, shivering, sweating, and vasodilation. In the Normal panel, vasoconstriction and non-shivering thermogenesis begin above 35 degrees Celsius, shivering begins below 37 degrees Celsius, marked with a blue dot, and sweating and vasodilation begin above 37 degrees Celsius. In the Anaesthesia panel, the thresholds for vasoconstriction and non-shivering thermogenesis shift left to below 35 degrees Celsius, shivering begins above 33 degrees Celsius with a blue dot, while sweating and vasodilation shift right to above 37 degrees Celsius.

FIG. 104.1 A schematic illustrating thermoregulatory thresholds in unanaesthetised and anaesthetised humans. Each response has its own threshold (x intercept) and gain. The interthreshold range is the distance between the first cold response (vasoconstriction) and the first warm response (sweating). (With permission from Sessler DI. Perianaesthetic thermoregulation and heat balance in humans. FSAEB J. 1993;7:638–644.)

A decrease in T_c initiates heat-preserving responses at a threshold of around 36.8°C beginning with sympathetic vasoconstriction. This can be followed, including in adults, by thermogenesis in brown adipose tissue where mitochondrial uncoupling protein causes metabolism to produce heat rather than adenosine triphosphate (ATP).[11] If T_c continues to fall towards 35.5°C, shivering begins, although being a highly metabolically demanding process, threshold and gain are reduced if the substrates for this process are inadequate, as may occur in hypoxaemia or hypoglycaemia.[1,2,12] Endocrine response includes increased secretion of thyroid-releasing hormone, cortisol and adrenaline.[11]

Preoptic neuronal expression of GABA decarboxylase stimulates GABA production, which is an important inhibitory neurotransmitter in thermoregulation.[2,5] GABA inhibits neurons that promote heat production, whilst GABAergic neurons are inhibited during cold.[2,5]

The net effect is maintenance of T_c around 36.9 ± 0.4°C, with circadian variation of 0.5°C–1.0°C, peaking in the evening and being lowest around 6 am.[7,13,14] Young children may exhibit greater diurnal variation, and T_c can vary between stages of the menstrual cycle. Older age, lower body mass index and hypothyroidism are associated with lower T_c. Haematological and solid organ malignancy can be associated with higher T_c or even fever through direct production of pyrogenic cytokines or tumour necrosis.[13,15] Whilst T_c is normally maintained in a narrow interthreshold zone, skin temperature may vary with ambient temperature and cutaneous blood flow. Temperature may vary amongst core organs including the brain by as much as 1.5°C during periods of rapid heat loss or gain. Whilst normal T_c is close to the upper limit of survival, it is well above the lower limit.[2,9]

Ability to regulate temperature diminishes in advanced age. Both threshold and maximum ability for peripheral vasoconstriction and thermogenesis is reduced, as are sweat gland output and ability to increase skin blood flow.[16,17] When able, the elderly compensate for diminished autonomic thermoregulation with behavioural mechanisms, however, this may be impaired by illness.[17] The elderly have lower T_c, and impaired ability to develop fever.[18]

Patients in the intensive care unit (ICU) frequently have disturbances of both heat production and heat loss. Anaesthetic agents and opiates significantly reduce the threshold for heat loss response in a dose-dependent manner.[19,20] Threshold for cutaneous vasoconstriction may fall to 34°C under anaesthesia (see Fig. 104.1); maximal response is also reduced by some agents, although gain is unaltered.[19,20] Sedative, adrenergic, cholinergic and neuromuscular blocking agents, exposure, intravenous fluids, impaired neurological or cardiovascular function and deficiencies of substrate for thermogenesis are common factors in ICU patients which can affect thermal homeostasis.[19,20]

Core Temperature Measurement

The temperature of blood perfusing the hypothalamus is considered the reference point for T_c, which can be measured by jugular venous bulb (JVB) catheterisation. This is most accurately approximated by an intravascular thermistor such as a pulmonary artery catheter (PAC).

During rapid temperature change, JVB temperature is closely approximated by PAC measurements except during, and for around 10 minutes after, rapid infusion of intravenous solution.[3,21,22]

Whilst accuracy at various sites can also be temperature range dependent, when core temperature is stable, compared with PACs[7,21-27]

- the most accurate measurements can be obtained from an oesophageal probe in the lower quarter of the oesophagus (0.11°C ± 0.3°C), or urinary bladder catheter (−0.2°C ± 0.2°C).
- Oesophageal temperature measured at the retro-cardiac region (T8-T9 vertebral level) closely approximates PAC, being adjacent to the left atrium and ventricle. Temperature, however, may be influenced by fluids being instilled into an adjacent nasogastric tube, and gas temperature in the trachea if placed too high (above tracheal bifurcation).
- Nasopharyngeal probe inserted to around 10–20 cm depth in adults approximates the internal carotid artery and is generally accurate.

- Rectal measurements can be accurate but should be placed to a depth of around 15 cm to approximate large pelvic arteries. Measurements can be unreliable, being more subject to faults in measurement conditions (such as location, faeces and mucosal inflammation), and can be inaccurate by more than 0.5°C.
- Urinary bladder catheter temperature measurements can be very accurate, especially around normothermic range, but rely on adequate urine output.

It is important to note that during periods of rapid T_c change, intravascular or oesophageal monitoring is preferred as lag can be significant from other sites due to thermal inertia of tissues and contents surrounding the thermistor.[7, 21, 22] There can also be differences of around 2°C between T_c and the brain, particularly in the presence of high cerebral metabolism from brain injury.[28] Brain temperature rather than T_c may be of interest in brain injury and during neuroprotective therapy, however, temperature targets are uncertain and guidance from clinical data remains based on T_c. Within the brain itself, cerebral thermo-pooling can occur with deeper regions warmer than surface regions by around 0.5°C–1°C. In brain injury, brain temperature lower than T_c (inverted temperature gradient) is a poor prognostic sign.[28]

Pharmacological Effects of Altered Body Temperature

Most work in this area has been performed on animal models; understanding of drug pharmacology in humans during hypothermia or hyperthermia is limited. Whilst each drug requires characterisation across temperatures, some principles provide guidance.[29-32]

Febrile patients with systemic inflammatory response syndrome (SIRS) may have high cardiac output with resultant increase in renal and hepatic blood flow. Augmented renal clearance of a number of antimicrobials has been well described in subgroups of ICU patients.[33, 34] Although hepatic blood flow may increase, the acute phase response suppresses expression of many cytokines and the net effect of fever on hepatic clearance in humans is uncertain. In severe hyperthermia, organ dysfunction may significantly alter pharmacokinetics. Notably, in severe sepsis and critical illness, multiple factors in addition to temperature derangement can alter drug pharmacology, including antibiotics.[33], [34]

Hypothermia can have a range of effects on pharmacokinetics and pharmacodynamics.[29-31] Absorption of orally administered drugs is significantly slowed. Effect on volume of distribution (Vd) is variable as tissue blood flow, protein binding and ionisation change. For example, the Vd of midazolam increases by 83% at 33°C, whilst the Vd of pancuronium decreases.[29] Altered ionisation is of significance in drugs with a pKa between 7 and 8 and narrow therapeutic window (e.g. lignocaine).[29] Hypothermia reduces hepatic blood flow and slows enzyme kinetics, resulting in reduced clearance. Pro-drugs have a slower onset, whilst active drugs and those with active metabolites have prolonged duration of action and increased risk of toxicity. Renal flow, glomerular filtration rate (GFR) and tubular secretion are also reduced.[35] In moderate hypothermia, clearance of propofol, morphine and vecuronium is reduced by 10%–25%.[29] Alterations in lipid solubility and tissue binding can also occur.

Experimental studies have raised concern that adrenergic receptor and second messenger system function can be significantly altered at temperatures below 30°C. Pharmacodynamic effect of α and β receptor agents may be significantly altered and differ between receptors and pharmacologic agents in severe hypothermia, with a tendency for blunted or even negative inotropic effect with some β receptor agonists such as epinephrine, but relative preservation of vasoconstrictive properties. Experimental studies have yielded varying results on cardiovascular pharmacodynamics in hypothermia.[36], [37]

Overall, pharmacologic changes with hypothermia are variable and poorly characterised. Rewarming can also bring about further kinetic and dynamic alterations. In patients with significant alterations in T_c it seems wise to dose parenterally, avoid pro-drugs and agents with multiple active metabolites, and where possible carefully dose to a clinical endpoint and use temperature-corrected therapeutic drug monitoring.

Acid-Base and Blood Gas Interpretation

Blood gas analysers are calibrated to perform measurements at 37°C. Deviation in body temperature from 37°C therefore results in a difference between the patient's values and those derived from the blood gas analyser, which may be clinically significant. [11, 38]

It is important to note that although the curve is non-linear, under most clinically relevant circumstances,

- PaO_2 changes by 5 mm Hg and $PaCO_2$ changes by 2 mm Hg for each 1°C change from 37°C
- pH changes by around 0.015 per 1°C change from 37°C (Rosenthal correction factor)

Clinical interpretation of blood gas and acid-base measurements according to alpha-stat and pH-stat methods may be relevant in the presence of thermal disorders and is covered in Chapter 57 .

Transcutaneous Pulse Oximetry Response Times in Hypothermia

In hypothermic patients, the detection of changes in haemoglobin oxygen saturation by transcutaneous pulse oximetry may be significantly slower using finger probes compared with forehead sensors. [39, 40]

Haemostatic Assessment

In the same manner as blood gas analysis, common tests of haemostasis including thromboelastograph, activated partial-thromboplastin time and prothrombin and thrombin times are measured with blood samples at 37°C. Hypothermic effects on platelet and coagulation enzyme function are reversible with rewarming and hence laboratory values may be misleading when considering the patient's haemostatic capacity. [41-44] Measurements performed at other temperatures require prior calibration of equipment.

Fever and Hyperthermia

Fever and hyperthermia are not interchangeable terms and have different clinical implications. Hyperthermia develops when temperature regulation is overwhelmed by endogenous or exogenous heat gain. The primary event is not cytokine-mediated, antipyretics are ineffective and T_c can be well in excess of 40°C. T_c greater than 41°C is usually due to hyperthermia rather than hyperpyrexia.[45] Because autoregulation has been overwhelmed, active temperature management is required.

Fever is the elevation of T_c which results from a change in the threshold of thermo-effector loops and therefore regulated thermogenesis. As such, physical measures to lower T_c may be counteracted by further activation of homeostatic mechanisms of heat conservation and production, and antipyretic agents which act against these mechanisms can be effective in lowering T_c. Additionally, thermogenic mechanisms increase metabolic rate and oxygen consumption by up to 13% for every 1°C rise in T_c produced.[46] There is no universally accepted T_c to define fever; 38.3°C remains a common threshold.[15, 47] The term hyperpyrexia is sometimes used for fever > 41°C.

Fever has a broad range of aetiologies (Table 104.1).[45, 47] The alteration in thermo-effector activation temperature is generated by pyrogenic substances which may be exogenous, such as microbial components including bacterial toxins and endotoxins (e.g. lipopolysaccharide), or endogenous ‘pyrogenic cytokines’ (IL-1, IL-6, interferons and TNFα). Exogenous pyrogens can also stimulate innate immune cell production of endogenous pyrogenic cytokines via toll-like receptors (TLR).[15] Pyrogens bind to receptors on circumventricular organs to up-regulate phospholipase A_2, which then results in prostaglandin E_2 production, hypothalamic warm-sensitive neuron stimulation and thermo-effector threshold shift.[1, 15] Notably, severe systemic inflammation can result in hypothermia, although these ‘cryogenic’ mediators are less well understood.[48]

Table 104.1

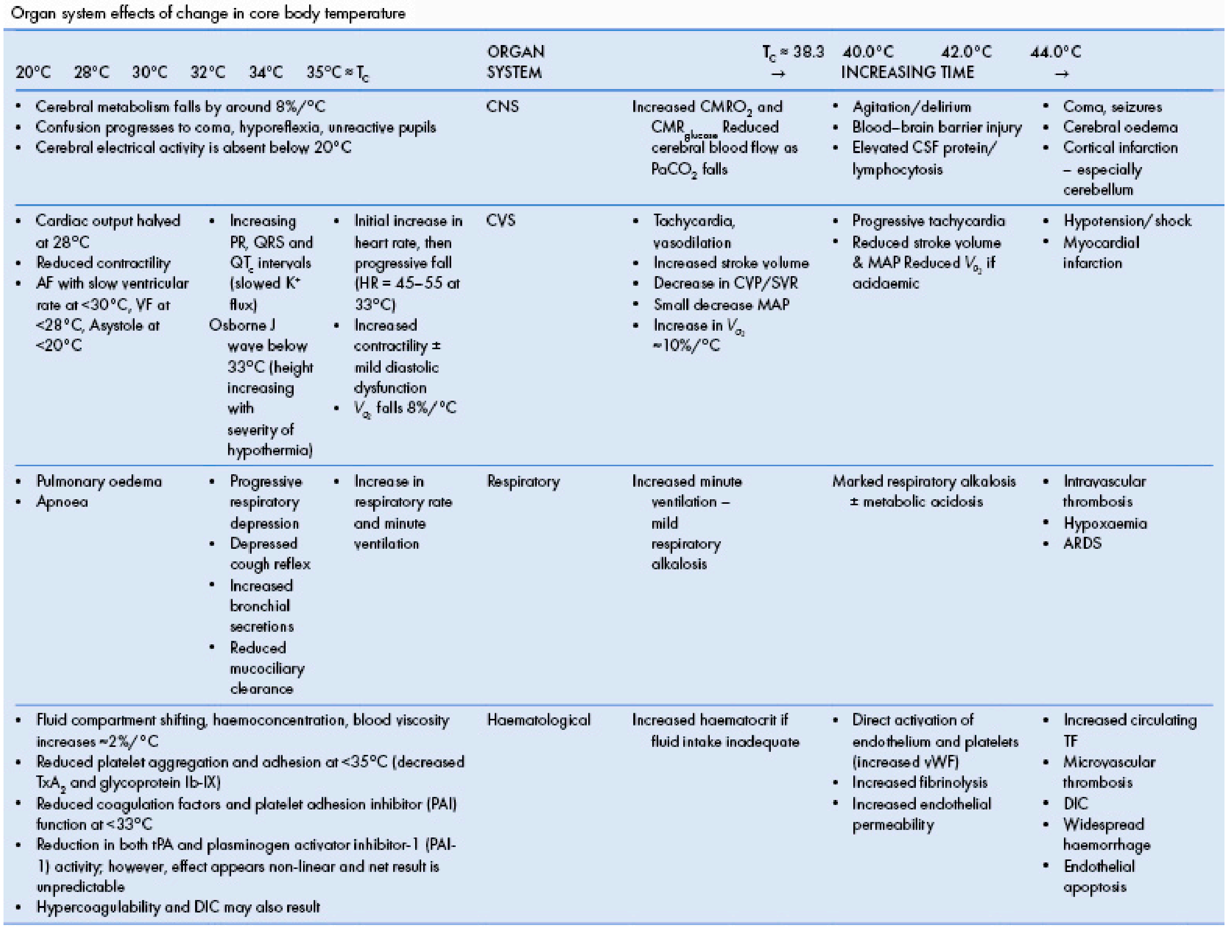
ARDS , Acute respiratory distress syndrome; *GBS* , Guillain–Barré syndrome; *GIT* , gastrointestinal tract; *SAH* , subarachnoid haemorrhage; *VILI* , ventilator-induced lung injury.

In various forms of brain injury including traumatic, ischaemic and haemorrhagic and when blood is present in the cerebrospinal fluid (CSF), fever is common and brain temperature can vary markedly from systemic temperature. [28] Mechanisms include injury or stimulation of hypothalamic regulation centres by blood and blood breakdown products, systemic inflammatory response to cellular injury and localised increases in cellular metabolism, hyperaemia, inflammation and disordered cellular respiration. [28, 49] Fever arising from disruption or localised stimulation of central temperature autoregulation centres in the brain is commonly referred to as ‘neurogenic’ or ‘central’ fever. [50, 51] Heat production by neuronal cell metabolism is a major determinant of brain temperature, and conversely, changes in brain temperature can alter neuronal metabolism. Intracranial heat dissipation is limited by the skull, and regions of injured brain can reach temperatures that exceed systemic by around 2°C. [28, 50]

Thermal injury

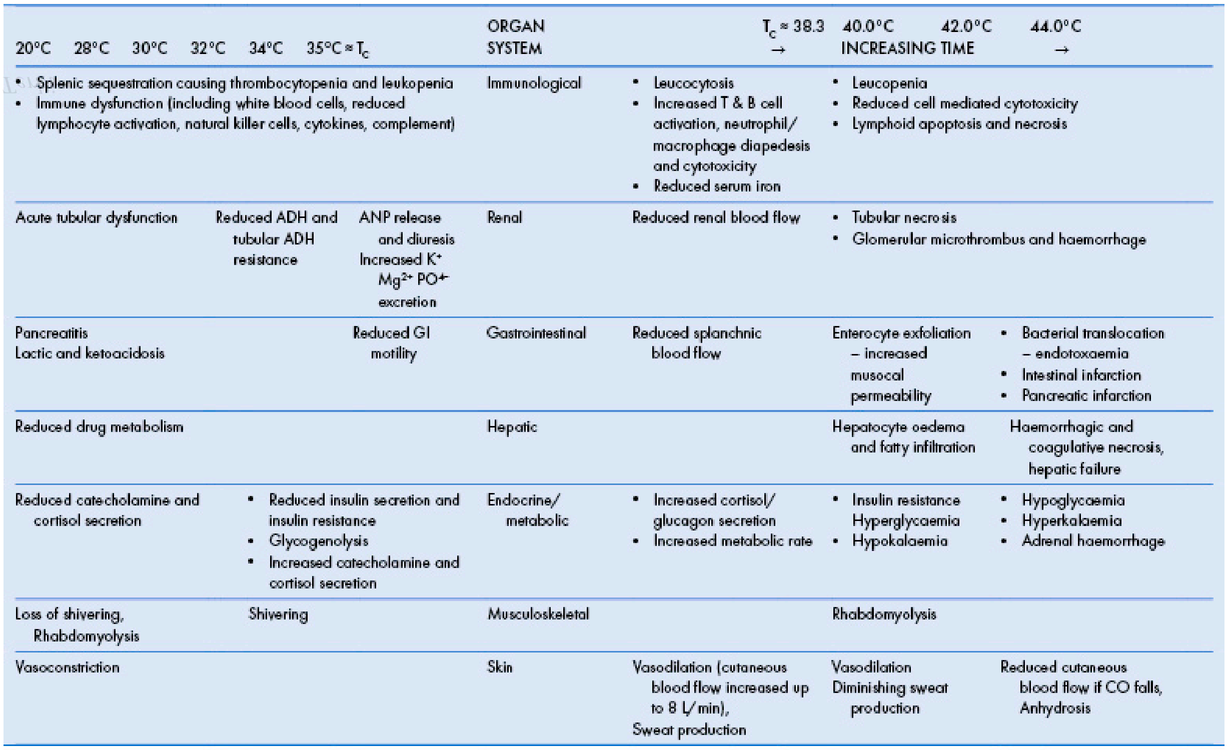
Severe elevation in T_c causes direct thermal cytotoxicity and triggers other mechanisms of cellular injury such as reactive oxygen species (ROS), systemic inflammatory and coagulation cascades, and apoptosis. [52] At cellular level, resistance to thermal injury varies between cell lines. [52] In general, short-term elevation in T_c to 40.0°C is thought to be well tolerated and upregulation of heat shock proteins (HSP) may provide transient protection from thermal injury. [51, 53-55] Beyond this, progressive damage occurs as T_c or exposure duration increases. [51, 52, 55] $T_c > 41.7°C$ or prolonged periods of $T_c > 40°C$ result in direct thermal injury to cells, with the central nervous system (CNS) being most vulnerable. [52] Thermal injury disrupts the blood–brain barrier as well as protein folding and therefore enzymatic function, ion channels and surface receptors, mitochondrial function, cytoskeletal elements and cell membranes with liquefaction.[52],[55] Major organ system effects as core temperature rises are summarised in Table 104.2 .

Table 104.2



Organ system effects of change in core body temperature

20°C 28°C 30°C 32°C 34°C 35°C ≈ T_C			ORGAN SYSTEM	$T_C \approx 38.3$ →	40.0°C 42.0°C INCREASING TIME	44.0°C →
• Cerebral metabolism falls by around 8%/°C • Confusion progresses to coma, hyporeflexia, unreactive pupils • Cerebral electrical activity is absent below 20°C			CNS	Increased $CMRO_2$ and $CMR_{glucose}$ Reduced cerebral blood flow as $PaCO_2$ falls	• Agitation/delirium • Blood–brain barrier injury • Elevated CSF protein/ lymphocytosis	• Coma, seizures • Cerebral oedema • Cortical infarction – especially cerebellum
• Cardiac output halved at 28°C • Reduced contractility • AF with slow ventricular rate at <30°C, VF at <28°C, Asystole at <20°C	• Increasing PR, QRS and QT_c intervals (slowed K^+ flux) Osborne J wave below 33°C (height increasing with severity of hypothermia)	• Initial increase in heart rate, then progressive fall (HR = 45–55 at 33°C) • Increased contractility ± mild diastolic dysfunction • V_{O_2} falls 8%/°C	CVS	• Tachycardia, vasodilation • Increased stroke volume • Decrease in CVP/SVR • Small decrease MAP • Increase in V_{O_2} ≈10%/°C	• Progressive tachycardia • Reduced stroke volume & MAP Reduced V_{O_2} if acidaemic	• Hypotension/shock • Myocardial infarction
• Pulmonary oedema • Apnoea	• Progressive respiratory depression • Depressed cough reflex • Increased bronchial secretions • Reduced mucociliary clearance	• Increase in respiratory rate and minute ventilation	Respiratory	Increased minute ventilation – mild respiratory alkalosis	Marked respiratory alkalosis ± metabolic acidosis	• Intravascular thrombosis • Hypoxaemia • ARDS
• Fluid compartment shifting, haemoconcentration, blood viscosity increases ≈2%/°C • Reduced platelet aggregation and adhesion at <35°C (decreased TxA_2 and glycoprotein Ib-IX) • Reduced coagulation factors and platelet adhesion inhibitor (PAI) function at <33°C • Reduction in both tPA and plasminogen activator inhibitor-1 (PAI-1) activity; however, effect appears non-linear and net result is unpredictable • Hypercoagulability and DIC may also result			Haematological	Increased haematocrit if fluid intake inadequate	• Direct activation of endothelium and platelets (increased vWF) • Increased fibrinolysis • Increased endothelial permeability	• Increased circulating TF • Microvascular thrombosis • DIC • Widespread haemorrhage • Endothelial apoptosis



20°C	28°C	30°C	32°C	34°C	35°C ≈ T_c	ORGAN SYSTEM	T_c ≈ 38.3 →	40.0°C INCREASING TIME	42.0°C	44.0°C →
• Splenic sequestration causing thrombocytopenia and leukopenia • Immune dysfunction (including white blood cells, reduced lymphocyte activation, natural killer cells, cytokines, complement)						Immunological	• Leucocytosis • Increased T & B cell activation, neutrophil/ macrophage diapedesis and cytotoxicity • Reduced serum iron	• Leucopenia • Reduced cell mediated cytotoxicity • Lymphoid apoptosis and necrosis		
Acute tubular dysfunction			Reduced ADH and tubular ADH resistance		ANP release and diuresis Increased K^+ Mg^{2+} PO^{4-} excretion	Renal	Reduced renal blood flow	• Tubular necrosis • Glomerular microthrombus and haemorrhage		
Pancreatitis Lactic and ketoacidosis					Reduced GI motility	Gastrointestinal	Reduced splanchnic blood flow	Enterocyte exfoliation – increased musocal permeability		• Bacterial translocation – endotoxaemia • Intestinal infarction • Pancreatic infarction
Reduced drug metabolism						Hepatic		Hepatocyte oedema and fatty infiltration		Haemorrhagic and coagulative necrosis, hepatic failure
Reduced catecholamine and cortisol secretion				• Reduced insulin secretion and insulin resistance • Glycogenolysis • Increased catecholamine and cortisol secretion		Endocrine/ metabolic	• Increased cortisol/ glucagon secretion • Increased metabolic rate	• Insulin resistance Hyperglycaemia • Hypokalaemia		• Hypoglycaemia • Hyperkalaemia • Adrenal haemorrhage
Loss of shivering, Rhabdomyolysis				Shivering		Musculoskeletal		Rhabdomyolysis		
Vasoconstriction						Skin	Vasodilation (cutaneous blood flow increased up to 8 L/min), Sweat production	Vasodilation Diminishing sweat production		Reduced cutaneous blood flow if CO falls, Anhydrosis

Hyperthermias

Major causes of hyperthermia are presented in Table 104.3 . Important aspects of some are discussed below.

Table 104.3

Differential diagnosis of hyperthermia

Environmental hyperthermia	**CNS disease**
Heat stroke	Status epilepticus Hypothalamic stroke Granulomatous disease
Drug-induced hyperthermia	**Infectious**
Malignant hyperpyrexia Neuroleptic malignant syndrome Serotonin syndrome Anticholinergic toxicity Sympathomimetic toxicity Salicylate toxicity MAOI toxicity Withdrawal (alcohol, benzodiazepines and baclofen)	Sepsis Encephalitis Meningitis Cerebral abscess Tetanus Malaria Typhoid
Endocrine disorders	**Psychiatric disease**
Thyrotoxicosis Phaeochromocytoma	Lethal catatonia

CNS , Central nervous system; *MAOI* , monoamine oxidase inhibitor.

Heat Stroke

Heat stroke results when heat gain exceeds thermoregulatory capacity, and T_c can reach levels where thermal injury and activation of inflammatory, coagulation and ROS cascades occur.[52, 56, 57] It is characterised by $T_c > 40°C$ and neurological dysfunction, ranging from restlessness to delirium, seizures and coma (Bouchama's definition).[57,58] Heat stroke may be classified as either exertional or non-exertional. Non-exertional heat stroke occurs following exposure to high ambient temperatures in those at the extremes of age, or with co-morbid disease or medication that affects thermoregulation (Table 104.4). Exertional heat stroke occurs in healthy individuals who undertake strenuous activity, generally in environments with high ambient temperature and humidity.

Table 104.4

ACEI , Angiotensin-converting enzyme inhibitor.

Our understanding of the pathogenesis of organ dysfunction in heat stroke remains incomplete. A systemic inflammatory cytokine response occurs, although some components such as HSP may be protective whilst TNF-α and IL-6 levels correlate with severity.[52,53,56-59] Pro- and anti-inflammatory cytokines may be suppressed during the onset of hyperthermia, then rise 2–4 hours after reaching maximal T_c.[58-60] Inflammatory and coagulation cascade activation, endothelial injury and dysfunction with DIC develop and failure of thermally sensitive megakaryocytes can further contribute to thrombocytopaenia.[52,57]

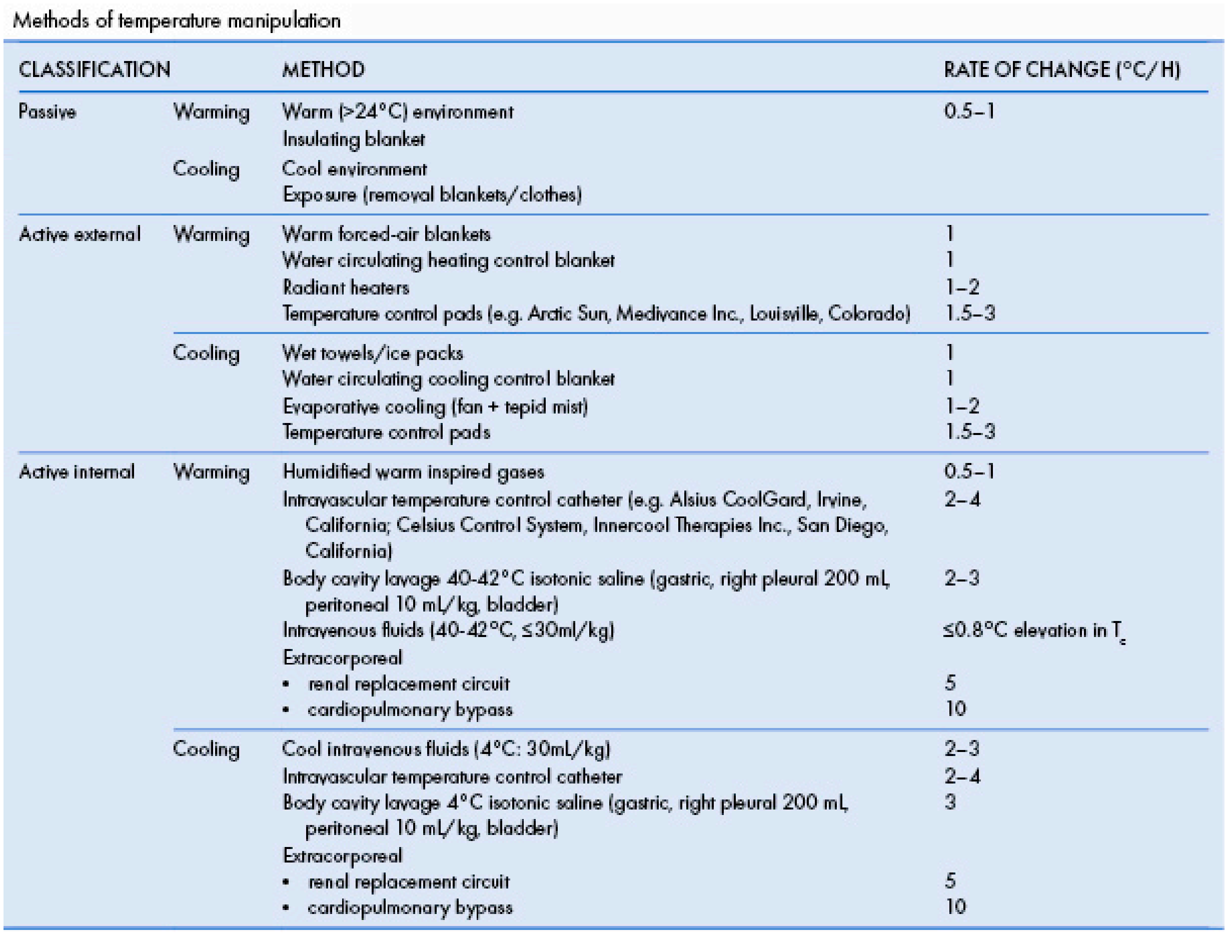
Reduced intestinal blood flow and oxidative cell membrane stress can damage cell junctions, resulting in translocation of endotoxins and potentially organisms from the intestinal tract.[52,56,61] Although routine antibiotics are not recommended, the possibility of translocation should be considered based on the clinical status of the patient.

Most patients with heat stroke present with delirium or coma, although focal neurology may occur. T_c is usually greater than 40.5°C and patients are vasodilated with multiorgan dysfunction. Sweating is often absent.[52] Disorders that may present in a similar fashion require exclusion (see Table 104.3).

Management is essentially supportive with rapid reduction to an initial target $T_c < 39.0°C$, ideally around 38–38.5°C (Table 104.5) with continuous temperature monitoring which remains accurate during rapid T_c

change. [56] Fluid repletion and increased minute ventilation are often required. Dantrolene remains under investigation; however, appears ineffective and skeletal muscle calcium is not thought to be a pathogenic mechanism of heat stroke. [56, 62] Antipyretics are ineffective and may worsen hepatic injury. [56, 58] Other experimental therapies of recent interest include allopurinol (for cell junction integrity), serine protease (suppression of pancreatic enzymes) and modulation of inflammatory and coagulation cascades with blood purification therapy, antithrombin III, recombinant activated protein C and thrombomodulin. [56, 57]

Table 104.5



Methods of temperature manipulation

CLASSIFICATION		METHOD	RATE OF CHANGE (°C/H)
Passive	Warming	Warm (>24°C) environment	0.5–1
		Insulating blanket	
	Cooling	Cool environment	
		Exposure (removal blankets/clothes)	
Active external	Warming	Warm forced-air blankets	1
		Water circulating heating control blanket	1
		Radiant heaters	1–2
		Temperature control pads (e.g. Arctic Sun, Medivance Inc., Louisville, Colorado)	1.5–3
	Cooling	Wet towels/ice packs	1
		Water circulating cooling control blanket	1
		Evaporative cooling (fan + tepid mist)	1–2
		Temperature control pads	1.5–3
Active internal	Warming	Humidified warm inspired gases	0.5–1
		Intravascular temperature control catheter (e.g. Alsius CoolGard, Irvine, California; Celsius Control System, Innercool Therapies Inc., San Diego, California)	2–4
		Body cavity lavage 40-42°C isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder)	2–3
		Intravenous fluids (40-42°C, ≤30ml/kg)	≤0.8°C elevation in T_c
		Extracorporeal	
		• renal replacement circuit	5
		• cardiopulmonary bypass	10
	Cooling	Cool intravenous fluids (4°C: 30mL/kg)	2–3
		Intravascular temperature control catheter	2–4
		Body cavity lavage 4°C isotonic saline (gastric, right pleural 200 mL, peritoneal 10 mL/kg, bladder)	3
		Extracorporeal	
		• renal replacement circuit	5
		• cardiopulmonary bypass	10

Recovery from hyperthermia can be biphasic, with initial hypothermia and then mild hyperthermia prior to restoration of thermal homeostasis. [63]

Traditional teaching has been to avoid hypothermia during recovery, however, in murine models prevention of hypothermia during recovery was associated with greater hypotension and mortality.[60]

Heat stroke mortality remains high with an in-hospital mortality of 65% being reported in a large, prospective observational study.[64] Survivors often have significant long-term morbidity, predominantly neurological impairment with the cerebellum being the most susceptible region to thermal injury.[52]

Malignant Hyperthermia

Malignant hyperthermia (MH) is an autosomal dominant pharmacogenetic myopathy with variable penetrance usually precipitated by volatile anaesthetics or depolarising muscle relaxants, linked in 70% of cases to a mutation in the ryanodine receptor RYR1.[65,66] Other candidate proteins include Calsequestrin-1 and dihydropyridine receptor.[67] Upon triggering, excessive release of calcium into the cytosol results in sustained excitation-contraction coupling, hypermetabolism with increased aerobic glycolysis and eventual anaerobic metabolism and metabolic acidosis.

Onset is usually within 2 hours of exposure, however, timing and speed of onset can vary, and not every episode of exposure to a triggering agent results in MH in susceptible individuals.[65,66] A prior history of volatile anaesthesia or suxamethonium without incident therefore does not rule out MH. Cardinal features are hypercarbia disproportional to minute ventilation, tachycardia, hyperthermia and generalised muscular rigidity, often beginning with masseter spasm.[65] Rhabdomyolysis and DIC can complicate severe cases.

Prevention in susceptible individuals includes flushing of ventilator circuits and use of activated charcoal filters on both inspiratory and expiratory limbs to minimise exposure to trace amounts of volatile anaesthetic agents.[68,69]

Immediate management includes the following[68]:

- Cessation of triggering agents, flushing ventilator circuit of volatile anaesthetic agent. Increase minute ventilation.

- Dantrolene 2.5 mg/kg intravenous bolus, repeated 5–10 minutely until hypercarbia and temperature respond, maximum initial dose 10 mg/kg (median required is 6 mg/kg), then doses of 2.5 mg/kg as required.
- Note that calcium channel antagonists in combination with dantrolene can cause severe hyperkalaemia.
- Supportive management including temperature control and complications.

Suspected cases should be referred for MH testing, which usually includes a caffeine/halothane contracture test and genetic screening for relatives of confirmed cases with RYR1 mutation.

Outcome of MH is good with mortality less than 10%. Additional resources are available at http://www.mhaus.org and https://malignanthyperthermia.org.au .

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction characterised by hyperthermia, muscle rigidity, mental state change and autonomic dysfunction. It typically occurs within a month of introduction or dose increment of an antipsychotic agent. Other drugs that antagonise central dopamine transmission or rapid cessation of central dopamine agonist may also precipitate NMS.[70, 71]

NMS is thought to occur as a result of central dopamine antagonism, predominantly at the D2 receptor. In the hypothalamus, this results in hyperthermia, whilst mesocortical and nigrostriatal blockade results in mental state change and extrapyramidal symptoms respectively. Loss of central integration gives rise to autonomic instability.[70, 72]

The clinical presentation is one of hyperthermia (usually <42°C), 'lead-pipe' rigidity, tachycardia, labile hypertension and delirium or coma. This may be accompanied by hypoventilation, diaphoresis, tremor, incontinence or mutism. Onset is usually over hours to days and the diagnosis requires exclusion of other conditions that may mimic NMS (see Table 104.3). Peripheral leucocytosis is common. Creatine kinase is usually above

1000 IU/L and can be much higher. Acute kidney injury (AKI) and DIC complicate severe cases. Neuroimaging studies and CSF analysis are normal in 95% and electroencephalography (EEG) shows generalised slowing. [72]

Differentiation from other hyperthermias relies predominantly on drug and environmental history, the presence of hypertonia rather than hypotonia (heatstroke) and absence of serotonergic features.

Treatment includes [71], [73] :

- Supportive management including temperature control and complications
- Cessation of any potentially causative agent or re-introduction of acutely withdrawn dopamine agonist
- Potential adjunctive therapies include
    - Benzodiazepines or central α-agonist for agitation, catatonia or seizures
    - Bromocriptine 2.5–5 mg enterally 8 hourly
        - may reduce extrapyramidal symptoms and mortality
        - however, may worsen hypotension or psychosis
    - Electroconvulsive therapy (ECT) appears safe and effective if NMS is prolonged or psychotic symptoms persist

Dantrolene may be considered in severe cases, however, there is no RYR1 abnormality in NMS and a meta-analysis concluded no clear benefit. [71], [72] Drug withdrawal and supportive measures are usually adequate and mortality is less than 10%. Psychiatric advice should be sought prior to re-introduction of antipsychotics, generally after 2 weeks from syndrome resolution; however, recurrence occurs in up to one-third of cases. [71]

Serotonin Syndrome

A wide range of drugs is associated with serotonin syndrome, including selective serotonin re-uptake inhibitors (SSRIs), selective norepinephrine re-uptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs; including linezolid and methylene blue), lithium, amphetamines, pethidine, fentanyl, tramadol, triptans and St. John’s wort.[71] Severe serotonin toxicity generally occurs only after concurrent use of two or more serotoninergic agents, usually an SSRI and MAOI, and is thought to be mediated predominantly via the $5HT_{2A}$ receptor.[71,74]

Severe serotonin toxicity presents with altered mental state (agitation, delirium, coma), autonomic stimulation (tachycardia, hyperthermia, diaphoresis and tremor) and neuromuscular excitation (clonus, hyperreflexia, rigidity). Features with greater specificity for serotonin toxicity which therefore help to distinguish it from other hyperthermias include hyperreflexia, lower limb or ocular clonus and myoclonus. Rigidity tends to be predominantly lower limbs.[71,74]

The Hunter Serotonin Toxicity Criteria can be used to guide treatment and predict likelihood of progression to severe toxicity.[75]

Management of severe toxicity involves resuscitation, withdrawal of offending agents, cooling and supportive care. Complications are similar to those observed in the other hyperthermias. Adjunctive therapies are of less importance. These include the $5HT_{2A}$ agonist cyproheptadine 4–8 mg enterally 6 hourly, or chlorpromazine if enteral administration is not possible.[71]

Sympathomimetic Toxicity

Hyperthermia may be precipitated by all centrally acting sympathomimetics by increasing release, inhibiting metabolism or preventing re-uptake of noradrenaline, serotonin or dopamine. As with other severe hyperthermias, delirium, coma, rhabdomyolysis, DIC and multiorgan dysfunction can occur. There are no specific therapies and whilst dantrolene has been advocated, there is insufficient evidence to support routine use.[71]

Antimuscarinic Toxicity

Peripheral antimuscarinic toxicity causes tachycardia, cutaneous vasodilatation, mydriasis, urinary retention and impaired sweating. Central toxicity gives rise to tremors, delirium and occasionally seizures. Severe hyperthermia is unusual and most antimuscarinic toxidromes require only drug withdrawal and passive cooling. Benzodiazepines can be helpful, and physostigmine may be effective in severe central toxicity.[76,77]

Management of Fever

Whether mild-to-moderate fever is beneficial, neutral or harmful is uncertain and may be aetiology dependent.[78-85] Whilst $T_c > 38.5°C–40.0°C$ and total fever burden in general are associated with greater morbidity and mortality in critical illness, this may be an epiphenomenon and controlling T_c may not necessarily improve outcomes.[78-83]

Suggested factors to consider when deciding whether to treat fever include its aetiology, magnitude and the patient's severity of illness.[55,78,79]

Fever in the context of acute brain injury, including ischaemic, haemorrhagic and traumatic insult, is generally considered to be significant since experimental and observational data suggest that elevated brain temperature causes secondary neurological injury in a dose-dependent manner.[12,28,49-51,84,86-88] Mechanisms include temperature-induced leucocyte accumulation and neuroinflammation, hyperaemia, intracranial hypertension, blood–brain barrier disruption, free radical production and increased metabolic rate.[12,28,51,88] Although benefit from controlled normothermia is yet to be conclusively demonstrated, both treatment and prevention of fever is generally recommended in this setting.[89]

Active treatment of mild-to-moderate fever is somewhat more controversial in the absence of acute brain injury.[78-82,84] Acceptable T_c in the febrile critically ill patient should take into consideration the magnitude and aetiology of fever and severity of illness.[78,79]

In general, fever burden (magnitude and duration) is associated with worse outcomes in critical illness, with higher temperatures appearing to carry greater risk, especially in non-infectious aetiologies.[78-81,85] The increase in demand by thermogenic mechanisms on metabolism, oxygen consumption and cardiac output may be relevant in some. Considering the potential vulnerability of critically ill patients, it is generally recommended to maintain $T_c < 41°C$ in these patients.[55,78,79] For less severe temperature elevation, it may be reasonable to consider the patient's physiologic reserve due to acute illness or comorbidity to determine T_c target; however, benefit from active temperature control on this basis remains to be conclusively demonstrated.[78,79,82]

It is possible that fever resulting from systemic inflammatory response to infection may be a protective response, with several components of immune function enhanced by elevated T_c.[46,55,78,79] In CNS infection, febrile temperatures impair replication of some pathogenic bacteria and appear not to be associated with worse outcomes.[78,79,84] In patients admitted to intensive care with systemic infection, fever in the first 24 hours is associated with lower mortality compared with peak T_c within normal range.[85]

Areas of uncertainty include the effect of antipyretics on patient outcomes, and whether some aspects, such as site or type of infection, acute lung injury and septic shock for example, require specific consideration with respect to fever control.[90-97] Controlling fever reduced vasopressor requirement in the SEPSIS-cool multicentre trial of patients with septic shock.[96] In experimental studies, increased T_c enhanced pulmonary neutrophil accumulation and lung injury in pneumonia, but improved bacterial clearance in peritonitis.[94,95] In a large, multicentre randomised placebo-controlled trial of patients with sepsis and temperature >38°C admitted to intensive care, early initiation of intravenous acetaminophen therapy produced a statistically significant but clinically very modest lowering of peak and mean daily average temperatures of 0.25 and 0.28 respectively, and resulted in no significant difference in length of stay, survival or adverse effects.[92]

Importantly, temperature control to hypothermic range may be harmful in sepsis. Therapeutic hypothermia (TH) in the CASS trial of patients with septic shock adversely affected haemodynamics and respiratory function and, similar to a trial of TH in bacterial meningitis, was terminated early with concerns over worsening survival.[98,99]

Control of fever or maintenance of normothermia in the non-sedated, non-intubated patient can be challenging if thermoregulation is intact with elevated T_c balance point. The application of physical modes of cooling without pharmacological measures to alter thermo-effector response results in undesired shivering with increased cardio-respiratory workload, and an increase in oxygen consumption between 40% and 100%. [100] Pharmacological alteration of thermo-effector pathways is therefore often effective, such as paracetamol and non-steroidal anti-inflammatory drugs. Paracetamol acts predominantly by central inhibition of cyclo-oxygenase and results in temperature reduction of 0.3°C–0.4°C, without inducing a counter-regulatory response. [101] Other agents that suppress thresholds for thermogenesis include magnesium, opiates, benzodiazepines, clonidine, dexmedetomidine, tramadol and ondansetron. [102, 103]

Hypothermia

Definition and Classification

Hypothermia is defined as core temperature less than 35°C and may develop due to abnormal thermoregulation or heat loss overwhelming thermoregulatory capacity. Important causes and contributing factors are summarised in Table 104.6 .

Table 104.6

CNS , Central nervous system.

Severity is somewhat arbitrarily classified by T_c as [21, 104]

- mild (32°C–35°C)
- moderate (28°C–32°C)
- severe (<28°C)
- profound (<24°C).

Hypothermia may also be classified as unintentional (often referred to as ‘accidental’), or intentional (such as in cardiopulmonary bypass [CPB], deep hypothermic arrest and TH). This can be further divided into [21, 104] :

- primary (intact thermoregulation)
- secondary (abnormal thermoregulation)

Physiological Effects of Hypothermia

Hypothermia alters a wide range of molecular and cellular functions, some of which form the scientific basis for TH. Prolonged or severe hypothermia causes progressive deterioration in organ function. $T_c < 30–32°C$, depending on age and comorbidity, is considered a risk factor for cardiac arrest.[21]

Table 104.2 provides a summary of the physiological effects of hypothermia. Notably, metabolic rate reduces by around 7% per 1°C fall in T_c (around 8% in the brain), and in primary hypothermia <32°C cardiac, respiratory and central neurological activity falls in a generally linear fashion in parallel with T_c.[105,106] Expected vital signs for temperature can be calculated at https://www.hypothermiascore.org/vital-signs .

Manifestations of the normal thermoregulatory response predominate in patients with cold exposure or very mild primary hypothermia (generally with T_c above 34°C); however, patients with abnormal thermoregulatory capacity (especially those with dysautonomia) may lack some of these features and are therefore more prone to developing secondary hypothermia. Of note, experimental sympathetic stimulation using the cold pressor test (ice water immersion of hands) causes normal coronary arteries to dilate; however, atherosclerotic coronary arteries and normal coronary arteries in patients with chronic systemic hypertension can constrict.[107-109]

The Swiss staging system describes five clinical stages of severity in primary hypothermia as a tool for estimation of T_c. Accuracy is somewhat limited with significant overlap between clinical stages and T_c range[110-112]:

- stage I – conscious and shivering (estimated T_c 32°C–35°C)
- stage II – impaired consciousness without shivering (estimated T_c 28°C–32°C)

- stage III – unconscious, vital signs present (estimated T_c 24°C–28°C)
- stage IV – no (or minimal) vital signs (estimated T_c 13.7°C–24°C)
- stage V – death due to irreversible hypothermia (estimated T_c <13.7°C)

Conscious state depression by hypothermia in the absence of confounding factors appears to be a reasonable tool to assess risk of hypothermic cardiac arrest.[113] The Revised Swiss System stages clinical severity based on the AVPU scale of response to stimuli (Alert, Verbal, Painful, Unconscious) and presence or absence of vital signs, whilst a similar Danish system stages patients as mild if awake, moderate if unconscious, and severe if vital signs are absent.[114, 115]

Correcting Hypothermia

Techniques

The various methods of increasing core temperature are summarised in Table 104.5 .

In general[21, 104, 116-121]:

- in patients with intact autoregulatory thermogenesis at Swiss stage I, passive rewarming alone may be adequate and elevate Tc by up to 2°C/hour
- Swiss stage II patients often require addition of active external warming, warming of intravenous fluids, cautious intervention and cardiac monitoring
- Swiss stages III and IV with haemodynamic compromise may require addition of active internal or extracorporeal circuit rewarming
- Hypothermic cardiac arrest is optimally treated using extracorporeal membrane oxygenation (ECMO) or cardiopulmonary bypass (CPB), which can achieve rapid rewarming and good patient outcomes if not complicated by preceding hypoxia or comorbidity.

Warmed intravenous fluids, generally to around 40-42°C, are an inefficient means of rewarming and carry with them the implications of volume and fluid content administration. 30ml/kg of warmed intravenous fluids may elevate temperature by around 0.2–0.8°C. [120] Thoracic lavage can rewarm at around 3°C/hour whilst gastric and bladder irrigation are less effective. [104]

Active temperature control devices use continuously measured Tc feedback to adjust a surface or intravascular interface and generally provide much greater control. Surface control devices are less invasive; however, they rely on a large surface area of suitable skin coverage and can cause skin damage, whilst intravascular devices carry some risk of thrombosis, bleeding and infection. [21], [122-125]

Extracorporeal techniques with renal replacement therapy circuits (even in the absence of overt renal dysfunction), ECMO and CPB are the most reliable and effective. [21], [104], [116-119] Renal replacement therapy using conventional intermittent and continuous therapy settings rewarms at around 2-4°C/hour, whilst ECMO and CPB are capable of much higher rates. [104], [116], [117] ECMO is favoured in the setting of cardiac arrest, however, associated complications appear to limit its overall benefit for patients with spontaneous circulation. [118], [119]

Management of Cardiac Arrest in Hypothermia

Cardiac output falls with significant hypothermia, and severe hypothermia can produce a clinical state which mimics prolonged circulatory arrest and poor prognosis with apnoea, asystole, unreactive pupils and areflexia. However, as metabolism reduces by around 7% (8% for the brain) for every 1°C fall in T_c, cardiopulmonary resuscitation (CPR) may maintain adequate oxygen delivery for periods much longer than the low-flow times which are associated with poor outcomes in normothermic patients. Good outcomes have been achieved after well in excess of 2 hours of CPR, although much of this relies on hypothermia having been the cause of a progressive and proportionate fall in cardiac output and eventual circulatory arrest.[11] Survival from hypothermic cardiac arrest has been achieved in patients with T_c around 12–13°C.[11, 105] In a very early report of induced hypothermia in a 51-year-old woman, a rectal temperature of 9°C was reached, with 45 minutes' cardiac standstill before initiation of surface rewarming, which gradually returned spontaneous circulation and apparently normal neurological function.[126] It is generally recommended that resuscitation continue until a T_c of at least 35°C is achieved in an arrested patient.[21, 112]

The Hypothermia Outcome Prediction after extracorporeal life support (HOPE) score can be used to estimate survival probability with the use of extracorporeal life support (ECLS) in cardiac arrest secondary to accidental hypothermia.[127] The score is based on age, gender, T_c, serum potassium, duration of CPR and presence of asphyxia. Elevated serum potassium is considered a marker of extensive tissue injury in these patients and is associated with poor prognosis.[127]

End-tidal CO_2 is commonly used to assess circulation during CPR, although caution against the use of universal threshold values for decision-making remains, especially for termination of resuscitation.[128] As expected, in hypothermic patients the $ETCO_2$ to $PaCO_2$ difference will be greater using alpha-stat compared with pH-stat, and the utility of low $ETCO_2$ value as a marker of poor circulation and prognosis under CPR is even more limited.[129]

In circumstances where interruption of CPR is considered potentially beneficial (e.g. for transportation to a more favourable environment or facility), it is considered reasonable to accept up to 10 minutes' initial delay in CPR followed by 5-minute periods of CPR interposed with periods of interruption for up to 5 minutes if estimated T_c is 20°C–28°C, and 10 minutes if T_c is less than 20°C.[112]

Rewarming is important in restoring perfusing cardiac rhythm in patients with ventricular fibrillation (VF) or ventricular tachycardia (VT) and may also resolve atrial arrhythmias, atrioventricular block and bradycardia. Pacing may be hindered by reduced cardiac responsiveness and is generally not considered necessary for bradycardia due to hypothermia.[112, 130]

The European Resuscitation Council Guidelines modification for resuscitation in hypothermic patients includes [113]:

- checking for vital signs for up to one minute
- for VT or VF persisting after 3 shocks, withholding further shocks until temperature is > 30°C
- withholding adrenaline until temperature is > 30°C, then increasing intervals between adrenaline administration to 6–10 minutes until > 35°C
- recommendation for mechanical chest compression to facilitate transport during arrest

It is noteworthy that the optimal timing and dose of cardiac arrest drugs are not known for normothermic or hypothermic patients, and the use of vasopressors remains controversial.[11,104,130] These recommendations for modifying resuscitation are based on concerns over cardiac unresponsiveness to and possibly injury from defibrillation, and reduced effectiveness of drugs or drug toxicity with repeated dosing due to reduced drug metabolism.[11,105,112] However, animal studies have found vasoactive drugs and defibrillation to be effective in hypothermia.[105,130,131] Currently, there is inadequate evidence to support strong recommendations to modify standard CPR algorithms in the setting of hypothermia. Using standard algorithms for defibrillation and vasopressor administration according to effect in the presence of hypothermia is considered acceptable.[104,130]

Target Rates and Potential Hazards of Rewarming

Whilst the physiological effects of hypothermia below T_c 32°C progress in a generally linear manner, such a linear and proportionate recovery does not necessarily take place with rewarming. Furthermore, hypothermia is frequently either secondary or accompanied by other factors which can complicate the physiological effects of rewarming.

Hazards of rewarming from hypothermia can be categorised as:

1. Haemodynamic and metabolic deterioration during rescue, intervention and rewarming
2. Possible neurological injury caused by rapid rewarming

Haemodynamic and metabolic deterioration during rescue, intervention and rewarming

Physical handling, procedural intervention and rewarming can precipitate a deterioration in patient condition referred to as 'rescue collapse'.[21, 104, 105, 112, 121] Various contributors include haemodynamic deterioration including arrhythmia, 'afterdrop' of core temperature with surface warming techniques, and metabolic instability. Rescue collapse generally occurs in patients with hypothermia of Swiss Stage III or greater magnitude.[104, 121, 130] Hypothermia has effects on cardiac pacemaker cell depolarisation, myocyte repolarisation and action potential duration which can be heterogenous across the myocardium.[105, 132, 133] Sympathetic tachycardia of mild hypothermia gives way to bradycardia below around 32°C, with prolongation of PR interval, QRS and QT interval.[105, 133] Below 30°C atrial fibrillation and Osborn waves are common, and risk of ventricular arrhythmia is significant.[11, 21, 104, 112, 134] Osborn waves are not always present and are not apparently related to risk of ventricular arrhythmia.[134] Additionally, prolongation of repolarisation may be particularly arrhythmogenic between 30 and 34°C.[105, 133] Asystole can develop with profound hypothermia. Significant arrhythmias may be spontaneous or electromechanically precipitated by movement and intervention, including ventricular contact by guidewire and central venous catheter (CVC).

Concerns over rescue collapse, in particular precipitation of arrhythmia, should not delay intervention or lead to undertreatment, although due care should be taken with CVC placement.[104, 112]

In patients who have become hypothermic due to surface heat loss, the temperature of the peripheral compartment may be much lower than the core compartment, especially with 'frost-bite'. Active surface rewarming of these patients may cause peripheral vasodilatation resulting in cold blood circulating to the core compartment. This ‘core temperature afterdrop’ may be mitigated by using concurrent active internal rewarming such as warmed intravenous fluids.[21, 104, 121]

Rewarming can precipitate haemodynamic deterioration termed ‘rewarming shock’, characterised by reduction in myocardial performance, alterations in vascular function including reduction in vascular resistance, increased capillary permeability and mismatch between oxygen consumption and delivery.[21, 104, 105] Although not completely understood, potential contributors include autonomic dysfunction, shivering, free radical oxidation, activation of inflammatory cascades and metabolic disturbances similar to post-ischaemic myocyte stunning such as sarcoplasmic reticulum dysfunction with calcium overload, uncoupled oxidative phosphorylation, troponin phosphorylation with abnormal myofilament calcium sensitivity, mitochondrial swelling and myocyte necrosis.[105, 134-140] Because these processes can continue beyond hypothermia, rewarming shock may persist beyond or even develop after rewarming.[105]

Hyperkalaemia, hypercalcaemia, hypermagnesaemia and hyperphosphataemia may develop due to extracellular shifting during rewarming.[134-136] The return of insulin sensitivity may result in potentially detrimental hypoglycaemia and high blood glucose variation.[134-136, 141-144]

Rewarming from accidental hypothermia therefore requires a careful balance between the adverse effects of prolonged hypothermia, and potential adverse effects of rapid rewarming. Poor response to Tc-appropriate rewarming as outlined above should lead to a careful search for underlying causes or comorbidity such as drugs, toxins, endocrinopathy and sepsis, and may be associated with higher mortality.[145, 146]

Neurological Injury with Rapid Rewarming

For up to days following primary brain injury, a range of neuro-destructive processes appear sensitive to both temperature and rate of rewarming, including seizures, disordered cerebral autoregulation, intracranial hypertension, cerebral microcirculatory disturbance, inflammation and excessive neuroexcitation with excess calcium, glutamate, ROS and nitric oxide.[134, 147-154] Correspondingly, experimental and clinical studies show worse neurocognitive function with rapid rewarming.[155-162] Discrepancy between cerebral and core temperatures during rewarming can widen, and harmful cerebral rebound hyperthermia can occur.[149, 158, 161]

Clinically, it is often difficult to ascertain the presence of or degree of primary neurological injury, and it is not well understood whether faster rates of rewarming are safer in the absence of primary injury. Studies of TH for cardiac arrest used slow and controlled rates of rewarming from mild-to-moderate hypothermia of around 0.1–0.5°C/hour; however, ideal or safe thresholds of rewarming rate remain poorly defined.[162, 163]

For patients who are mildly hypothermic and comatose after achieving ROSC from cardiac arrest, the European Resuscitation Council and European Society of Intensive Care Medicine recommend against active rewarming to normothermia (good practice statement).[163]

Conversely, in traumatic brain injury unintentional hypothermia present on hospital arrival is associated with worse outcomes, and avoidance of hypothermia is generally recommended.[164]

Neurological injury during hypothermia and rewarming in the absence of primary brain injury

Whether cerebral hypothermia itself or rapid rewarming in the absence of primary brain injury can cause primary neurological injury is not completely understood. Apparently complete neurological recovery has been achieved after rewarming from 9°C, despite a period of greater than 45 minutes' cardiac standstill.[126] In severe accidental hypothermia, rates of rewarming around 9°C/hour via CPB have resulted in good neurological outcomes.[160]

Rapid rewarming may affect cerebrovascular autoregulation in a manner relevant to brain injury.[165, 166] Extracorporeal rewarming at rates greater than 5°C/hour in the treatment of accidental hypothermic cardiac arrest is associated with poorer neurological outcomes compared with slower rates;

however, data is observational, and it is also difficult to confidently separate those with concurrent primary brain injury from those without. [160]

Collectively, experimental and clinical data point towards less favourable neurological outcomes with rapid rates of rewarming. Taken together with the systemic risks of rapid rewarming described above, rewarming from hypothermia should be a balance between the urgency for rewarming and patient stability or risk. In hypothermic cardiac arrest, rapid and reliable rewarming at a rate of up to 5°C/hour is favoured and optimally provided by ECMO or CPB. Stable patients with spontaneous circulation may better be managed using slower and less invasive rewarming therapies. Once hypothermia is mild, in the absence of clinical urgency to correct hypothermia such as major haemorrhage, rewarming rates of 0.1–0.5°C/hour, similar to those used in clinical trials of mild hypothermia, seem justified. [122]

Therapeutic Hypothermia and Targeted Temperature Management

The potential for therapeutic hypothermia (TH), and/or the prevention of fever (therapeutic normothermia, TN) to reduce cellular insult in ischaemic, reperfusion and traumatic injury is the subject of intense interest and ongoing clinical research. [105] CNS injury, particularly ischaemia-reperfusion, remains the focus of intense interest and research focus. Table 104.7 lists some of the effects of hypothermia with potential benefits for the CNS.

Table 104.7

From Polderman KH. Induced hypothermia and fever control for prevention and treatment of neurological injuries. *Lancet* . 2008;371:1955–1969.

Targeted temperature management (TTM) encompasses TH and TN for the mitigation of temperature-sensitive tissue injury mechanisms and includes not only setting the target T_c, but also any rate of temperature change.

TTM for patients who achieve return of spontaneous circulation with CPR and neonatal hypoxic-ischaemic encephalopathy is covered in Chapter 30 .

TH may be effective for the treatment and prevention of elevated intracranial pressure (ICP); however, it is a complicated and potentially hazardous intervention, data on its effect on patient outcomes is sparse and potential for benefit may vary according to cause.[167]

Whilst TH can reduce ICP in traumatic brain injury (TBI), clinical studies have so far failed to demonstrate benefit. The EUROTHERM trial of TH for the treatment of refractory intracranial hypertension (ICP > 20 mm Hg persisting after 5 minutes of initial treatment) was terminated early due to possible worsening of mortality in the TH group, with at best an outcome of futility had the study been completed.[168] Early prophylactic TH reduced ICP but did not impact neurologic outcome or mortality in the POLAR study.[169] Questions remained over its utility in severe TBI following these studies, and expert consensus in 2020 deemed consideration of mild TH (T_c 35–36°C) amongst other third-tiered therapies to be reasonable in patients with raised ICP but normal brain tissue oxygenation.[170] Of concern is rebound intracranial hypertension on rewarming.[171]

Cerebral oedema is a major cause of death in acute hepatic failure; fever avoidance and TH are considered reasonable for control of ICP in this setting.[172, 173]

TH is also of interest in other conditions, however, given its complexity and risks more supportive data is required to determine its utility. Conditions studied include ischaemic and haemorrhagic cerebrovascular accident, traumatic brain and spinal cord injury, status epilepticus, myocardial ischaemia and cardiogenic shock.[105, 174-187]

As discussed above, important trials of TH in sepsis have raised concerns over likely worsening of survival.[98, 99]

Electrical safety and injuries

Christina HY So, Christopher Pak-to Lee and Po Tong Chui

Introduction

Electrical injuries result in an estimated 1000 deaths and 5% of burns centres admissions in the United States each year.[1], [2] Electrically injured patients may require intensive care unit (ICU) management. Patterns of presentation include post-cardiopulmonary arrest, coma, myocardial injury, blunt trauma and severe burns – either direct or indirect from electric currents, arcs, fires and explosions. An understanding of the physical concepts and mechanisms of injuries helps in the assessment and management of these patients.

Physical Concepts

Electricity is the movement of negatively charged electrons. A *potential difference* or voltage, measured in volts (V), exists between two points if the number or density of electrons is greater at one point. When these points are connected by a conductor, the potential difference will cause the flow of an *electric current* (I), measured in amperes (A). *Resistance* (R), measured in ohms (Ω), opposes this flow of electrons. Ohm's law describes the relationship of voltage, current and resistance:

$$V = IR$$

When an electric current flows through a conductor, electric energy is converted to heat energy. Joule's law describes the energy measured in joules (J) produced over time (t):

$$J = VIt = I^2Rt$$

A current that flows in one direction, is called a *direct current* (*DC*). Electricity to homes, hospitals and factories is supplied as an *alternating current* (*AC*), which flows back and forth at 50–60 Hz. Static electricity has no free flow of electrons. Insulated objects can become highly charged, usually by repeated friction. The charge is dissipated by electrons jumping onto an adjacent object with a potential gradient. 'Jumping' electrons ionise and heat the air medium, causing a spark, which may ignite flammable liquid or gas. Lightning is a type of static electrical discharge.

Electrophysiological Considerations and Determinants of Extent of Injury

Electric current flows through the victim's body when it completes a circuit. Dry intact skin has a resistance greater than 100,000 Ω, [3] offering some protection for the body. In general, electric current flows from its source to earth through the victim's body, following the path of least resistance.

The main determinants of the extent of electric injuries include the following [4, 5]:

1. Electrical factors
    a. total electric current
    b. type of current AC or DC

    c. duration of contact
2. Body factors
    a. current pathway
    b. tissue electrical resistance
    c. current density
    d. body mass
3. Environmental factors
    a. moisture, fluids

Systemic effects and tissue damage are directly proportional to the total electric current delivered (see Table 105.1). The interplay of voltage, current, resistance and duration of contact is described by Joule’s law above. At low voltage, AC is more harmful than DC. AC at 50–60 Hz is prone to induce tetanic muscle contractions, resulting in an inability to release hand grip or ‘cannot let go’. Tetany of respiratory muscles leads to suffocation. The repetitive stimulation of AC on the myocardium can induce ventricular fibrillation.

Table 105.1

The current pathway determines which tissues and organs are injured. Current pathways through the thorax or the central nervous system (CNS), such as hand-to-hand or hand-to-foot pathways, are more likely to produce serious injuries discussed below. Body tissues exhibit different electrical resistance. Tissues with low electrical resistance, such as nerves, blood vessels, muscles and mucous membranes, are exposed to more severe injuries. Current density, being current per unit cross-sectional area, also determines the pattern of injuries. In the arm, current density is higher around the elbow. The joint consists mainly of high-resistance tissues such as bone and tendon on cross-section. Electric injuries to blood vessels, nerves and muscles tend to be more severe around joints.

Similarly, with the same total current delivered, patients with low body mass will be exposed to higher current density and more severe injuries. The current required to induce ventricular fibrillation also correlates with body mass. [6] Skin protection against electrical shock is lost in wet environment. Under such circumstances, for example in the bathroom, electrocuted victims may not have skin burns.

Mechanisms of Injury

Electrical injuries can occur by direct and indirect mechanisms:

1. Direct electro-physiologic effects: causing depolarisation and tetany of nerves, muscle and myocardium.
2. Electroporation: when an electrical current creates pores and disruption to cell membranes, leading to reversible and irreversible cell injuries of nerves and muscles. [7]
3. Thermal injury by the conversion of electrical to thermal energy. Muscles, small blood vessels and nervous tissue are particularly susceptible. Electrothermal burns to skin and internal tissue and organs are major causes of morbidity and mortality.
4. Indirect and delayed complications: including rhabdomyolysis, compartment syndrome and vascular ischaemia with myocardial and brain infarcts.
5. Secondary trauma: High-voltage AC and DC can cause the victim to fall or be thrown, resulting in blunt traumatic injuries. Lightning bolts lead to rapid heating of surrounding air with shock waves and blast injuries. [8]

Causes and Patterns

Different sources of electricity produce different patterns of electric injuries (Table 105.1):

1. *Low voltage* (<1000 V): usually occurs indoors in the home or office setting, resulting in diverse direct and indirect injuries from superficial burns, muscle spasms and deep tissue injuries, to cardiorespiratory arrest. At low voltage, AC produces more severe and extensive injuries than DC.
2. *High voltage* (>1000 V): usually occurs outdoors in occupation-related settings. The current is often transferred via an arc into or

over the body, generating extremely high temperatures and severe thermal injuries with deep burns. It also causes violent muscle contraction and secondary traumatic injuries.

3. *Conducted electrical weapons (CEWs) such as Tasers used by the police:* CEWs deliver AC or pulsed DC currents at up to 50,000 V in 5-second pulses. The electric current causes uncontrolled muscle tetanic contraction, known as Taser shock, with risks of secondary traumatic injuries, thermal injury resulting from the conversion of electrical energy to thermal energy and cardiac arrhythmias. [9]
4. *Lightning* : delivers about 300 million V and 30,000 A over a few milliseconds. Lightning strikes can be classified as direct strike, side splash, contact injury and ground currents. Injuries are the results of electric currents on and through body tissues, burns and blast injuries with barotrauma, flying debris and blunt trauma. [10]

Macroshock versus Microshock

Macroshock occurs when an electrical current passes through the skin into the body. Microshock occurs when the current is delivered directly to the myocardium via intra-cardiac electrodes or catheters. Electric shock to a small area of the myocardium may trigger ventricular fibrillation with an extremely small current below 100 μA.

With the advent of open-heart surgery and cardiac catheterisation in the 1960s, the hazards of microshock became widespread concerns. In studies of laboratory animals and humans during cardiopulmonary bypass, ventricular fibrillation can be induced with a very small current of about 60–80 μA. [11] Safety organisations have introduced stringent electrical safety standards and limit leakage currents to below 10 μA for at-risk patients. However, because of the absence of documented clinical reports, there is controversy on the magnitude of the hazards of microshock. [12]

Injuries by Organ Systems

The damage from electrical injuries can be wide ranging (Fig. 105.1). Determining the likely voltage will provide an estimate of the total current delivered. High-voltage injuries are more likely to be complicated by deep tissue and/or internal organ injuries.

Exit wound

The anatomical illustration shows a man grasping an electrical wire above his head with his left hand, identifying it as the entry wound location, and the right hand resting on a metal railing is labelled as the exit wound. The body is semi-transparent, exhibiting internal organs and the path of current flow. Multiple organ systems are labelled with potential injury effects. The brain is associated with cerebral infarct, intracranial haemorrhage, and acute cranial nerve deficit. The spinal cord is labelled with myelopathy. The lungs are associated with chest wall burns, respiratory arrest, and respiratory muscle paralysis. The heart is labelled with arrhythmia, including ventricular fibrillation, asystole, heart block, and conduction defect, as well as myocardial damage and ischemia. The muscle is associated with rhabdomyolysis and compartment syndrome. The vascular system is labelled with aneurysm formation, rupture, and coagulation necrosis. Skin is labelled with burns. Peripheral nerve effects include mononeuropathy, and the bone is associated with periosteal burns.

FIG. 105.1 High-voltage electric shock: Current pathway and direct organ and tissue injuries. (Reproduced with permission from Beatrix Yu, The Department of Anaesthesia and Intensive Care, The Chinese University of Hong Kong.)

Cardiovascular Injuries

Arrhythmias

Arrhythmias are the most common cardiac complications of electric injury. Exposure to high-voltage DC and lightning can cause asystole. Low-voltage AC can induce ventricular fibrillation by a small current with an arm-arm or arm-leg electrical pathway passing through the thorax. [2] Other dysrhythmias such as sinus tachycardia, supraventricular tachycardia, atrial fibrillation and premature ventricular complexes can also occur. Most arrhythmias occur soon after the injury but delayed arrhythmias 8–12 hours after the event have been reported. [13]

Conduction Abnormalities

Conduction defects can present with various degrees of sinus bradycardia, heart block, bundle-branch block and prolonged QT interval. Cardiac injury caused by AC appears to have a predilection for sinoatrial and atrioventricular node dysfunction, probably by direct electric disruption, and ischaemia and infarction of the right coronary artery. [14]

Myocardial Injury

Damage to the myocardium can occur due to electrothermal injury, electroporation, myocardial contusion from trauma and anoxic injury when respiratory arrest occurs prior to cardiac injury. This can lead to severe left and right ventricular dysfunction, Takotsubo cardiomyopathy and regional wall motion abnormalities. Rare manifestations include ischaemia secondary to coronary artery spasm or thrombosis and cardiac rupture. [15-17] Non-specific ST and T wave changes can also occur. [1]

Vascular Injuries

Blood vessels may become thrombosed and occluded as a result of the thermal injury. Small vessels are at greater risk, as the blood flow in larger vessels dissipates the heat. Delayed aneurysm formation, arterial thrombosis and rupture have also been reported. [2]

Neurological Injuries

Neurological injuries may be central or peripheral, and immediate or late in onset.

Direct Injuries

Acute cranial nerve deficits, intracerebral haemorrhage, cerebral infarcts and seizures can occur when electrical currents pass through the brain parenchyma. Spinal cord injury, for example C4-8 myelopathy may occur when electrical current traverses arm-to-arm. [2] Late complications include epilepsy, encephalopathy, neuropsychologic sequelae, memory disturbance and parkinsonism. [18], [19]

Indirect Injuries

Anoxic brain injury can occur secondary to cardiorespiratory arrest, and head or spinal cord injuries can occur secondary to trauma.

Peripheral Nerve Injuries

Mononeuropathy is the most frequent peripheral neuropathy following low-voltage electrical injury, which may occur as a direct effect of electricity passing through the body or delayed effect due to scar formation. Other injuries include multiple bilateral mononeuropathies, polyradiculopathy and peripheral polyneuropathy. [20]

Specific to Lightning Injuries

Keraunoparalysis is a transient, reversible paralysis associated with severe vasoconstriction. Reversible autonomic abnormalities can also occur leading to hemodynamic instability and bilateral dilated pupils.

Respiratory Injuries

Direct Injuries

Direct lung parenchymal electrical injuries are rare.

Respiratory arrest immediately following an electric shock may be caused by direct electrical injury to the respiratory control centre, prolonged tetanic contraction or paralysis of respiratory muscles or a combined cardiorespiratory arrest secondary to ventricular fibrillation or asystole.

Indirect Injuries

Chest wall burns, traumatic rib fractures and lung contusions can impair respiratory movement and gas exchange.

Renal Injuries

Direct

Direct electrical injuries to the kidneys are unusual.

Indirect

Renal injuries can occur in relation to anoxic injury, hemodynamic compromise, hypovolemia, rhabdomyolysis and sepsis.

Skin and Musculoskeletal Injuries

Skin injuries vary from local erythema to full-thickness burns. Entry and exit wounds are diagnostic of electric injury. High-voltage injuries produce extensive necrosis of deeper tissues. The severity of skin burns must not be used to assess the degree of internal injuries. Lightning produces partial thickness linear burns in areas of high sweat concentration. Punctate burns are clustered circular burns where an electric current exits the body. Lichtenberg figures are fern-like skin patterns pathognomonic of lightning injuries. Skin resistance is markedly reduced by moisture. The flashover effect facilitates the dissipation of considerable current. Full-thickness burns are rare, occurring in less than 5% of lightning patients. [21]

Electrothermal injury can lead to widespread tissue necrosis, burns and oedema resulting in compartment syndrome and rhabdomyolysis. Direct bone injuries include periosteal burns, destruction of bone matrix and osteonecrosis. [8] Uncontrolled muscle contractions caused by AC and DC may produce long bone and spinal vertebrae fractures. [22]

Other Injuries

Ophthalmological

Cataract is the most common complication and may occur in up to 5% of victims with electric injuries above the neck. Other complications include uveitis, hyphema, vitreous haemorrhagic and optic nerve injury. [8], [23]

Ear

Tympanic membrane rupture, sensorineural hearing loss, vertigo and tinnitus have been reported in lightning-injured patients. [24]

Gastrointestinal

Direct injury is uncommon and can occur from vascular injury leading to mesenteric ischaemia. Oral burns can occur in children biting electrical cables.

Management of Electrical Injuries

Initial Resuscitation

Apnoea is the critical factor in mortality after electrical injury. Respiratory support will be needed for muscle paralysis after high-voltage injury as it will persist for several hours. Patients in cardiac arrest are managed according to advanced cardiac life support protocols. [25] Ventricular tachycardia (VT) or ventricular fibrillation (VF) are treated with defibrillation. Respiratory arrest often outlasts cardiac arrest. Ventilation must be continued after the return of spontaneous circulation. [26]

Favourable outcomes have been reported in patients with cardiac arrest after severe electrical injury because many patients are young without pre-existing cardiopulmonary disease. [27] Prolonged CPR is recommended even in patients with an initial rhythm of asystole, especially with lightning injuries. Similarly, fixed dilated pupils may be the result of autonomic dysfunction rather than brain insult, and should not affect the decision to provide resuscitation. [28]

Trauma Approach

Secondary trauma during an electrical accident can produce severe blunt and penetrating injuries. The initial approach should include a systematic and comprehensive trauma evaluation. In particular, the cervical spine should be immobilised, and IV access should be avoided in any limb involved in the current pathway as vascular structures may be damaged.

History and Physical Examination

History should be obtained from the patient, witnesses and first responders to ascertain details of the accident and mechanisms of injury, including voltage exposure, AC or DC, duration of exposure, explosion, falls and environmental conditions such as outdoor or indoor, presence of fluids and moisture. Careful, comprehensive and repeated examinations are required to detect tissue and organ injuries.

Burns

The entire skin surface should be examined for burns, particularly in the palms, soles, skin folds, creases and joints. Apart from the depth and extent of burns, entry and exit wounds provide information about the current pathway. Deep injuries may not be detected by physical examination alone.[1] Skin injury may underestimate the extent of underlying tissue damage. Any patient with full-thickness skin burns should be assumed to have deep tissue injury. There may be characteristic burn patterns, such as punctate burns in lightning, and kissing burns (flexor surface burns that occur in sustained muscle contraction causing current to flow across a flexor joint, such as the antecubital fossa, often associated with extensive tissue injury) in high-voltage electric arc injuries.[29], [30]

Musculoskeletal

The soft tissues, bones and spine should be palpated for evidence of fractures, and signs of compartment syndrome. Pain upon joint movement is suggestive of the presence of bone or muscle injuries.

Neurological

A comprehensive neurologic examination is required to detect brain, spinal cord and peripheral nerve injuries. Findings may include impaired consciousness level, focal neurologic deficits, abnormal pupillary reflexes and spinal cord signs. Peripheral nerve lesions may produce patchy sensory or motor changes.

Cardiac

History and physical examination may reveal the current pathway and provide clues to possible cardiac involvement.[31] The patient should be examined for arrhythmias and evidence of myocardial injury such as chest pain and hypotension.

Others

In patients with blast injuries, tympanic membranes should be inspected for rupture. Ophthalmologic evaluation is indicated as soon as medically feasible for victims with visual loss or electric injuries above the neck. [26]

Investigations

Investigations are indicated to detect organ injuries. Blood tests should include baseline complete blood count and renal function tests. Investigations for rhabdomyolysis or compartment syndrome include creatine phosphokinase (CK) and electrolytes, particularly potassium, calcium and phosphate. CK indicates muscle injury much better than burn surface area. All patients should have an electrocardiogram (ECG). Troponin will be required for suspected myocardial damage.

Imaging for trauma such as X-rays and computed tomography (CT) should be performed as indicated. A cranial CT scan is warranted for any patient presenting with altered mental status, known trauma to the head, loss of consciousness, seizure or any focal neurological deficits. Imaging of the cervical spine may also be considered according to trauma protocol. The possibility of acute myelopathy should be evaluated as soon as possible to avoid further injuries. [20]

Hospital and Intensive Care Unit Management

Severity of Injury and Triage Considerations

Some patients with electrical injuries only have minor symptoms, while others sustain life-threatening complications as detailed above. Information from history, physical examination and investigations are useful for risk stratification. High-voltage injuries are associated with greater morbidity and mortality. However, burns and the need for surgery are also common in low-voltage injuries and should not be underestimated. [32] In general, patients with low-voltage injury, no history of loss of consciousness and a normal ECG may be discharged safely home after a short period of observation. Patients with ECG abnormalities should be monitored for 24 hours for delayed cardiac arrhythmias. ICU admission is required for severe burns or organ dysfunction in high-risk patients (see Table 105.2).

Table 105.2

High-risk factors of electrically injured patients

History	High-voltage injury Loss of consciousness Chest pain Significant trauma
Physical examination	Burns Soft tissue injuries Transthoracic electrical pathway
Investigations	Arrhythmias ECG abnormalities Significant elevation in CK or troponin

ICU Management

There is no specific therapy for electrical injury. Management is supportive and directed towards the treatment of skin and soft tissue burns, and cardiac, neurologic, respiratory, and renal complications. [25]

1. Fluid resuscitation

   Patients with significant soft tissue injuries may need aggressive fluid resuscitation to restore volume and perfusion and to reduce the risk of acute kidney injury from rhabdomyolysis. Isotonic crystalloid is usually used initially. Standard protocols according to surface burn area may result in insufficient fluid replacement for internal fluid loss. Fluids should be targeted to physiological parameters such as heart rate, blood pressure and urine output.[33] The goal is to maintain end-organ perfusion while avoiding fluid-related morbidities such as tissue oedema and limb and abdominal compartment syndromes. In selected patients with severe burns, ‘colloid rescue’ with albumin or fresh frozen plasma can be considered to avoid sustained high-volume crystalloid resuscitation.[34], [35]

2. Burns and wound management

   Burn wounds may be superficial or deep, and in general, are treated similarly to thermal burns. Tetanus toxoid prophylaxis is administered according to vaccination status. Patients with extensive burns should be referred to a specialist burn unit for surgical intervention. Pain control is also an important component of burn wound care.

3. Musculoskeletal

   Patients are at risk of developing acute compartment syndrome, especially in the first 48 hours. They require frequent neurovascular assessment of the extremities and serial monitoring of CK.[36] Technetium 99m nuclear scanning may help to detect ischaemic muscle,[37] and magnetic resonance imaging (MRI) can identify oedematous muscles in deep tissue injuries.[38] Compartment pressures greater than 30 mm Hg or within 10–20 mm Hg of diastolic pressure indicate the need for surgical decompression with escharotomy or fasciotomy to prevent further muscle necrosis and tissue ischaemia.[39] Compared with thermal burns, electric burns patients are more likely to require surgical decompression, serial necrosectomies, flap reconstruction and amputation. Early and radical debridement of nonviable tissue is crucial to improve outcomes. Amputations are often necessary to enable survival. Decisions may require a judgement of tissue viability, expected functional outcome, sepsis and multi-organ failure complications.[40]

4. Cardiac

   Cardiac complications such as arrhythmias, conduction abnormalities and myocardial dysfunction are treated according to standard practices. Patients with high-risk factors (see Table 105.2) should have continuous cardiac monitoring, preferably in the ICU, even if there is no external injury.[41] Further specific workup may be indicated. In patients with myocardial dysfunction, echocardiography or cardiac MRI may reveal hypokinesia or fibrosis secondary to myocardial damage. Patients with myocardial ischaemia should undergo coronary angiography to look for possible underlying coronary artery disease, arterial spasm or thrombosis caused by electrical injuries. Implanted cardiac electronic devices need to be interrogated to exclude electrical damage.[31]

5. Renal

   Maintaining intravascular volume and adequate urine output is the main approach to preventing acute kidney injury from hypovolemia or rhabdomyolysis. In the presence of significant myoglobinuria, targeting a higher urine output of 1–2 mL/kg/h is recommended until CK is on a decreasing trend. Alkaline diuresis to achieve a urine $pH > 6.5$ using sodium bicarbonate can be considered.[42] Persistent rise of CK should prompt a search for a source of ongoing muscle ischaemia. In established renal failure, fluid overload should be avoided and renal replacement therapy should be started according to standard indications.

6. Abdominal

   Supportive care for abdominal complications, such as gastroparesis and ileus includes nasogastric suction and intravenous fluids.[43] Stress ulcer prophylaxis is administered especially in those unable to tolerate enteral nutrition.

7. Summary

   The immediate outcome and long-term prognosis are determined by cardiorespiratory arrest, severe electrothermal burns, myocardial damages, nervous system injuries and secondary multisystem organ failure. There is no specific therapy for electrical injury, and ICU management requires diligent assessment and meticulous organ and life support. Prevention remains the best way to minimise the prevalence and severity of electrical injury. Regulatory agencies should ensure electrical installation and equipment comply with up-to-date standards. The public should be educated on electrical safety at home and work.

Electrical Safety in Intensive Care

In the ICU, medical electric equipment needs to be in physical contact with the patient for monitoring, diagnosis and treatment. These applied parts can be sensors, electrodes, cables or indwelling catheters, which are often intravascular, or even intra-cardiac. Applied parts increase the risks of electrical injuries as they allow electrical currents to enter the body directly.

Multiple electrical equipment also needs to be deployed in proximity, producing risks of electric overload and fault and leakage currents. Intravenous medications and fluids, body fluids, dialysis and irrigation solutions may cause a wet environment that increases electric hazards to patients and staff. ICU electric safety is a vital component of hospital occupational and patient safety programmes. [44]

Medical-Electrical Safety Codes and Standards

The International Electrotechnical Commission (IEC) sets global standards for hospital electrical safety. IEC 60601-1 standards ensure the safety and performance of medical-electrical equipment in normal and fault conditions. [45] The standards have been adapted into local standards, including EN 60601 (Europe), BS EN 60601-1 (UK), UL2601-1 (USA), CSA C22.2 (Canada) and AS/NZ 3200-1 (Australia/New Zealand).

Medical-Electrical Equipment Classifications

The IEC 60601-1 specifies two classifications for the design and construction of medical electric equipment in electric safety:

1. Power source: classified according to the method of protection
    - Class I: provision of a protective earth connection to the internal and/or external conductive parts of the power source.
    - Class II: provision of an additional layer of insulation either by double insulation (two layers of insulation) or by Reinforced Insulation (typically by double thickness insulation).
    - The term ‘Class III’ is used for equipment that is powered by safety extra-low voltage AC (<25 V) or DC (60 V). However, this equipment class is not recognised by IEC 60601-1 as the limitation of voltage is not considered sufficient for patient safety.
2. Applied parts: classified according to degree of protection
    - Medical-electrical equipment has different areas of application and therefore different electrical safety requirements. The Standards define three types of applied parts with increasing risk levels:
        - Type B (Body): Applied parts which are generally not conductive and may be connected to the earth.
        - F-type applied part: Applied parts which are electrically connected to the patient must be floating, that is, electrically isolated from earth and other parts of the medical

equipment. F-type applied parts are either type BF or type CF.

Type BF (Body floating): applied parts in conductive contact with the body but not the heart. Examples are blood pressure monitors, convective body warmers and ultrasound equipment.

Type CF (Cardiac floating): applied parts suitable for direct cardiac connection. Examples are ECG monitor, infusion pump, temporary external pacemaker, dialysis machine and invasive cardiac output monitor.

Each of these three types of applied parts can be defibrillation-proof (see Table 105.3).

3. Medical locations

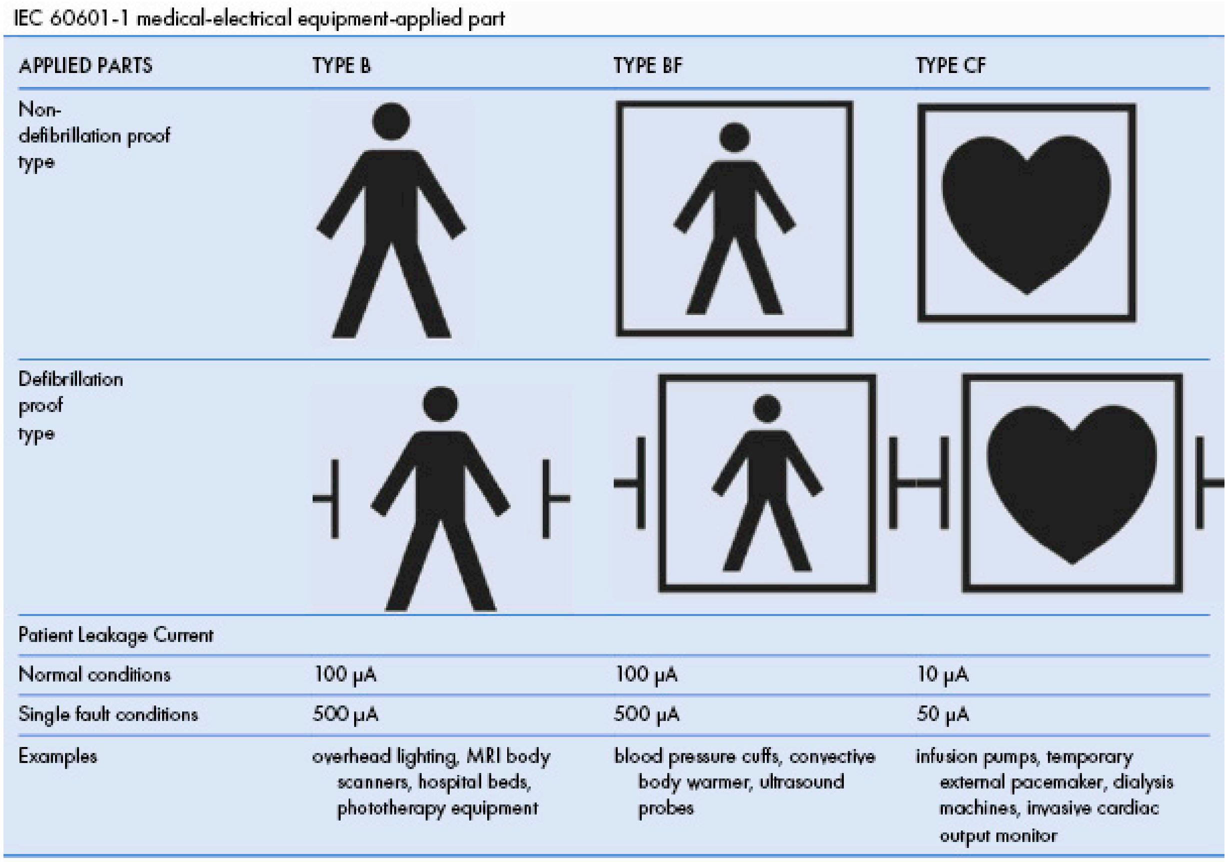
The IEC 60364-7-710, AS/NZS 3003 and AS/NZS 3000 classify medical locations as:

Group 0: Patient area rooms, where no applied parts are intended to be used, for example consultation room or outpatient areas.

Group 1: Body-protected rooms, where applied parts are intended to be used externally or invasively to any part of the body, except the cardiac zone.

Group 2: Cardiac-protected rooms; where applied parts are intended to be used in applications such as intra-cardiac procedures, operating theatres and ICU and where electric failure can endanger patient safety.

Table 105.3



IEC 60601-1 medical-electrical equipment-applied part

APPLIED PARTS	TYPE B	TYPE BF	TYPE CF
Non-defibrillation proof type			
Defibrillation proof type			
Patient Leakage Current			
Normal conditions	100 μA	100 μA	10 μA
Single fault conditions	500 μA	500 μA	50 μA
Examples	overhead lighting, MRI body scanners, hospital beds, phototherapy equipment	blood pressure cuffs, convective body warmer, ultrasound probes	infusion pumps, temporary external pacemaker, dialysis machines, invasive cardiac output monitor

Electrical Fault and Leakage Currents

A fault current is an electric current in an unwanted conductive path under fault conditions. The most common electrical faults are earth and short circuit faults. Insulation breakdown allows inadvertent contact between a live wire and the metal enclosure in an earth fault. The return path of the earth fault current is normally through the earth wire but can also be any person or equipment connected to the earth. A short circuit fault occurs when the live wire contacts the neutral directly. Arcing or sparking can occur as electrical current jumps from live to the neutral wire, with risks of causing fires and explosions.

A leakage current is an electric current in an unwanted conductive path under normal operating conditions. Leakage currents exist in all medical electric equipment. These are caused by inductance and capacitance induced by AC currents. Depending on the point of contact, leakage currents can lead to:

- earth leakage current that flows to earth via the earth conductor of protectively earthed equipment,
- touch current (formerly enclosure leakage current) that flows from an accessible conductive part to earth via a conductor other than the earth conductor and
- patient leakage current that flows through a patient connected to the equipment-applied parts.

Leakage currents are usually small and barely perceivable but can potentially cause microshock in susceptible ICU patients. For medical electric equipment, IEC standards specify stringent safety limits for leakage currents to be below 10 μA (see Table 105.1).

Measures to Protect Staff and Patients

Electrical Fault Protection

The fundamental rule of electric fault protection is that hazardous live parts shall not be accessible, and accessible conductive parts shall not be hazardous. Harmful electrical contact can be categorised into contact with live parts (direct contact) and contact with conductive parts in fault conditions (indirect contact). The corresponding protective measures are basic and fault protection.

For medical electric equipment, basic protection includes insulation and protective earth connections. Fault protection includes reinforced or double insulation, automatic power disconnection, isolated power supply and equipotential bonding. The principle is that no safety hazard should occur under ‘single fault conditions’, such as failure of basic insulation, interruption of protective earth and external voltage on an applied part.

Protective Earth Connection

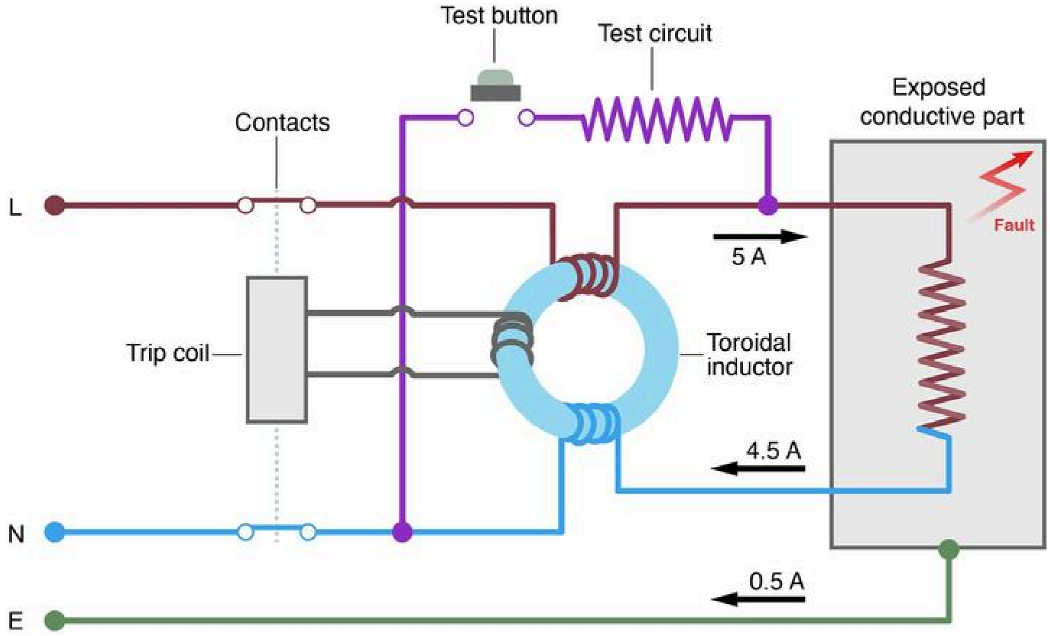
The earth (also known as the ground in the United States and Canada) connects all accessible metal parts of the electrical equipment, including the enclosure and non-current carrying parts, to the earth. Both the neutral and earth are at 0 V relative to the earth. Protective earth will provide a low-resistance path directly to earth, enabling immediate diversion of fault currents. Properly earthed medical equipment will ensure most fault and leakage currents flow to earth, instead of patients or staff. With the appropriate devices, the electric current passing through the earth connection will also trigger the disconnection of the power supply.

Protective earth as basic protection is often overlooked, underprovided and even defective without proper maintenance. [46] IEC60601-1 specifies that the resistance must be $<0.1\ \Omega$ on equipment with a detachable power cord and $<0.2\ \Omega$ for equipment with a fixed power cord.

Residual Current Device with Automatic Power Disconnection

Residual current device (RCD) is a generic term used for describing devices which incorporate residual current protection. Residual current circuit-breaker (RCCB) in the United Kingdom, Europe, Australia and New Zealand is termed ground fault circuit interrupter (GFCI) in the United States and Canada. These are built into the socket outlets in the hospital settings.

An RCD monitors the earth leakage current in a circuit. It is constructed from coils of wire wound around a ferrite toroid core, one for each live conductor of the circuit being protected. A current imbalance between the live and neutral conductor induces a voltage in the tripping coil. This will disconnect the electrical supply to the protected circuit (Fig. 105.2).



Test button
Test circuit
Exposed conductive part
Contacts

0.5 A
E

The schematic diagram of a residual current device circuit includes labelled components and current paths. The left side features a live wire labelled L and a neutral wire labelled N, connected through contacts and a trip coil. A test button and test circuit are shown above the trip coil. The live and neutral wires pass through a toroidal inductor, which also connects to a trip coil. On the right, an exposed conductive part is shown with a fault path symbol. Current measurements are indicated along the path, that is 5 amperes flow from the live wire toward the exposed part, 4.5 amperes return through the neutral wire, and 0.5 amperes are diverted through the green earth wire labelled E.

FIG. 105.2 Residual current device with automatic power disconnection. (Reproduced with permission from Beatrix Yu, The Department of Anaesthesia and Intensive Care, The Chinese University of Hong Kong.)

To reduce the risk of electrocution, RCDs should operate within 25–40 ms with any fault currents greater than 30 mA. In New Zealand, the medical grade RCD has a 10-mA trip current.

Isolated Power Supply

Isolated power system (IPS) supplies electrical power that is ‘isolated’ and not referenced to earth. An isolation transformer supplies power via two conductors (lines 1 and 2), analogous to live and neutral conductors in conventional earth-referenced power systems. Both systems include a third earth conductor. However, the neutral is referenced and connected to earth in the conventional power system, but not the IPS. When a person contacts a single conductor in IPS, no shock occurs since the electrical circuit is incomplete. IPS affords better electrical safety than protective earth connection as the latter depends on the integrity of a low impedance earth return path.

Electrical hazards are increased in a ‘wet’ patient care area, in which fluids may collect or drench on the floor or work area, in proximity to patient or staff. If the patient care area is classified as a wet location, then RCD or IPS must be installed. RCD is allowed only when interruption of power can be tolerated. Thus when classified as a wet location, IPS is the only option in ICU.[47]

A line isolation monitor (LIM) checks the integrity of earth isolation by monitoring the potential for current flow from IPS to earth. The LIM alarms when faulty equipment connects the IPS to the earth, reducing the impedance to the earth to under 24,000 Ω and making an earth fault current over 5 mA possible.

When the LIM alarms, immediately unplug the last piece of electrical equipment. If plugging that piece of equipment again causes the LIM to alarm, remove that equipment from use. Otherwise, continue to unplug electrical equipment until the LIM alarm stops. If a vital piece of equipment (e.g. defibrillator and ECMO machine) is causing the LIM alarm, it can continue to be used. However, the protection of IPS is no longer functional.

Equipotential Bonding

Equipotential bonding is the electrical connection of exposed conductive parts of electrical equipment and extraneous conductive parts of non-electrical items to an earthing system. This ensures zero potential difference among all accessible conductive parts even under fault conditions. When an equipotential zone is established within the patient care area, staff and patients in contact with electrical equipment and metal objects are at the same electrical potential and 0 V with reference to earth. This will minimise the risks of microshock caused by leakage currents (Figs. 105.3 and 105.4).[47], [48]

The illustration depicts an electric current fault scenario involving a patient and a practitioner. On the left, a practitioner touches a medical equipment unit labelled as having a defective earth connection. The equipment is connected via a power cord with an earth prong, shown enlarged in a circular inset. The current travels from the defective equipment through the practitioner hand and into an external pacemaker, which is connected by pacing wires to a patient lying on an electric bed. The patient, shown in frontal view with directional arrows along the chest and leg, is grounded by a wet bed sheet that connects to earthed metal parts of the bed. Another inset shows a close up of the power plug with a functional earth connection.

The diagram illustrates the electrical safety infrastructure linking an electrical room and an intensive care unit room. On the left, the electrical room contains an isolation transformer connected to a monitoring system with a line isolation monitor. Three wires labelled L (live), N (neutral), and P E (protective earth) extend from the transformer. A protective earth bar is installed inside the transformer cabinet, and an equipotential bonding busbar is mounted adjacent to the room. Green wires from the busbar connect to various outlets and fixtures, including taps and pipes. On the right, the I C U room includes an alarm panel, a medical pendant with electrical and gas outlets, a hospital bed, a ceiling light, and medical equipment such as a dialysis machine.

Technology [47] ; Reproduced with permission from Beatrix Yu, The Department of Anaesthesia and Intensive Care, The Chinese University of Hong Kong.)

Emergency and Uninterruptible Power Supplies

Failure of the power supply in the ICU may interrupt life support medical equipment with potentially fatal consequences. Emergency power supplies shall automatically provide backup power within a pre-set changeover time. For most essential power supplies with a standby generator, a break of 15 seconds is required, and this will only be acceptable for general equipment such as electric beds, fluid warmers, body warming devices and sterilising equipment. For life support equipment, an online uninterruptible power supply (UPS), consisting of a rectifier/charger, battery, inverter and a static switch, capable of a no-break backup power supply will be necessary. UPS should be capable of providing power for at least 3 hours. This can be reduced to 1 hour if the standby generator is capable of up to 24 hours of power supply. [47]

Electrical Safety Policy and Programme

Electrical safety requires collaborative efforts between management and frontline staff. Hospital management should provide an electrical safety programme, defining the policies and procedures for managers, supervisors, workers, contractors and even visitors. In turn, staff are required to implement and follow the electrical safety programme and should receive training on the safe use of medical-electrical equipment and to report incidents and defective equipment for investigations and preventative actions. [49] On-site biomedical personnel can carry out regular maintenance and testing of equipment. The person can also provide technical support and troubleshooting of alarms and faults in clinical areas. [50]

Envenomation

Catherine L. Tacon, Mark Little and Christopher Peter Nickson

Envenomation by snakes, hymenopteran insects (bees, ants and wasps), arachnids (spiders, scorpions and ticks) and marine creatures can be life-threatening or cause serious illness, both via direct toxicity of venom and allergic reaction to the venom. This chapter focuses on some of the 66 venomous species found in Australia. It is recommended to consult a clinical toxicologist for immediate local advice on management through the relevant Poisons Information Centres (Australia 13 11 26, New Zealand 0800 764 766 (0800 POISON), UK 0870 6006266, USA 1 800 222 1222).

Snakebite

The World Health Organisation (WHO) has deemed snakebite a neglected tropical disease, which predominantly affects agricultural workers and children in regions of the world where health care services are poor. As such the data is poor. The WHO estimates that 5.4 million people are bitten by snakes each year, with up to 2.7 million cases of envenoming and more than 130,000 deaths annually. The WHO has a roadmap which aims to reduce morbidity and mortality from snakebite by 50% by 2030 through community engagement, improving health care systems and ensuring safe, effective treatment, including the strengthening of regulations regarding production and access to antivenoms. [1]

This section will focus on snakebite in Australia, where envenoming after a snakebite is rare.

Epidemiology

Of the estimated 3000 people bitten by snakes annually, 200+ people receive antivenom and only 1–2 deaths occur. Rates of snakebite and envenoming are much higher in tropical Australia compared to southern Australia. In Darwin, Northern Territory, the reported rate of snakebite is 23.2/100,000 population/year with a rate of envenoming 7.9/100,000 population/year. [2] By comparison, in Perth, Western Australia, the snakebite rate is 1.92/100,000 population/year and the envenoming rate is 0.5/100,000 population/year. [3]

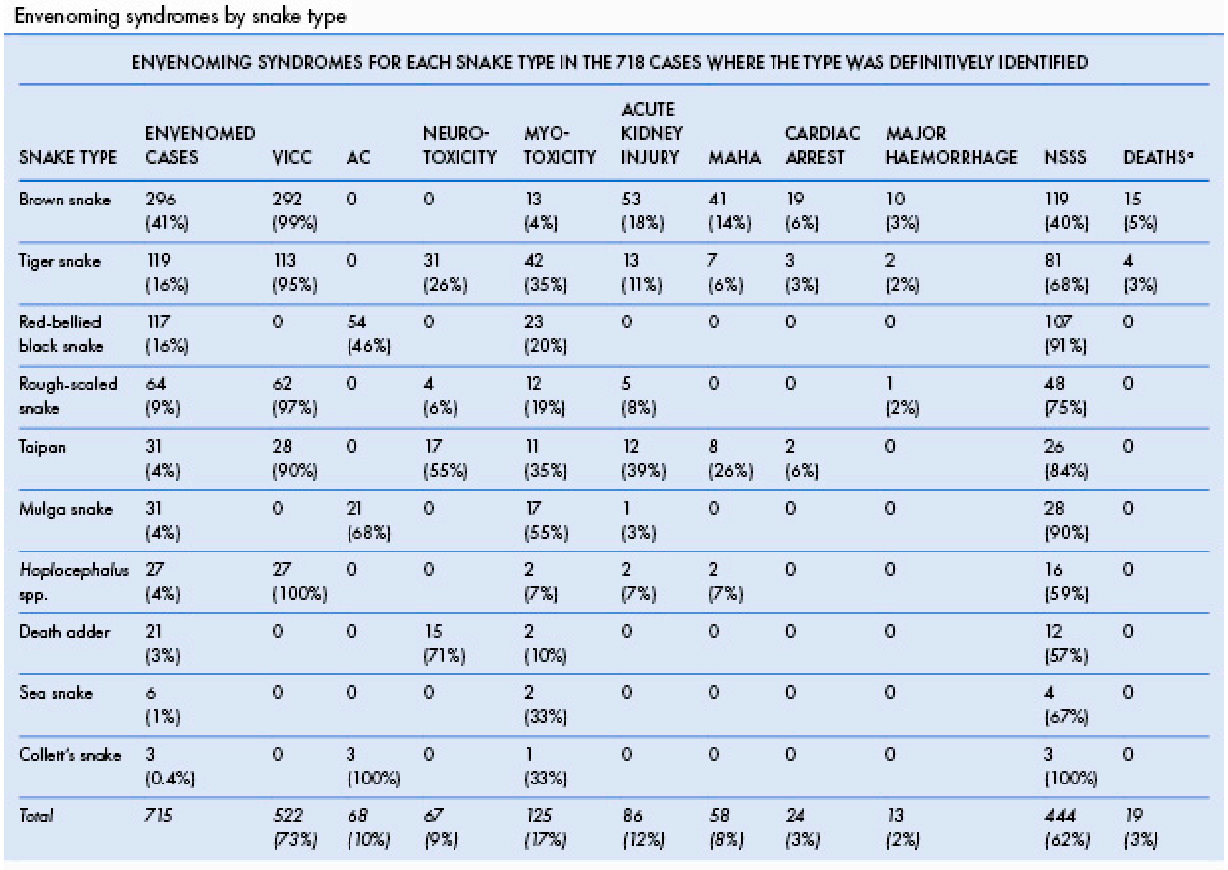
The Australian Snakebite Project (ASP) reported 1548 cases of snakebite of which 835 were envenomed over 10 years. [4] The median age was 37 (IQR 23–53), with 73% being male. The majority of bites were to limbs (lower limb 52% and upper limb 42%); two reports were of bites to the head. Nearly all deaths were due to brown snake envenoming; the rate of cardiac arrest in brown snake envenomed patients was 6%, and overall mortality was 5%.

Snake Venoms

The role of the venom of snakes is to acquire and help in the digestion of prey. The major effects of snake venom are coagulopathy, paralysis or rhabdomyolysis, although there are other toxins within Australian snake venoms.

The envenoming clinical syndromes as shown by the ASP are shown in Table 106.1 .

Table 106.1



Envenoming syndromes by snake type

ENVENOMING SYNDROMES FOR EACH SNAKE TYPE IN THE 718 CASES WHERE THE TYPE WAS DEFINITIVELY IDENTIFIED

SNAKE TYPE	ENVENOMED CASES	VICC	AC	NEURO-TOXICITY	MYO-TOXICITY	ACUTE KIDNEY INJURY	MAHA	CARDIAC ARREST	MAJOR HAEMORRHAGE	NSSS	DEATHS[a]
Brown snake	296 (41%)	292 (99%)	0	0	13 (4%)	53 (18%)	41 (14%)	19 (6%)	10 (3%)	119 (40%)	15 (5%)

Total	*715*	*522* *(73%)*	*68* *(10%)*	*67* *(9%)*	*125* *(17%)*	*86* *(12%)*	*58* *(8%)*	*24* *(3%)*	*13* *(2%)*	*444* *(62%)*	*19* *(3%)*

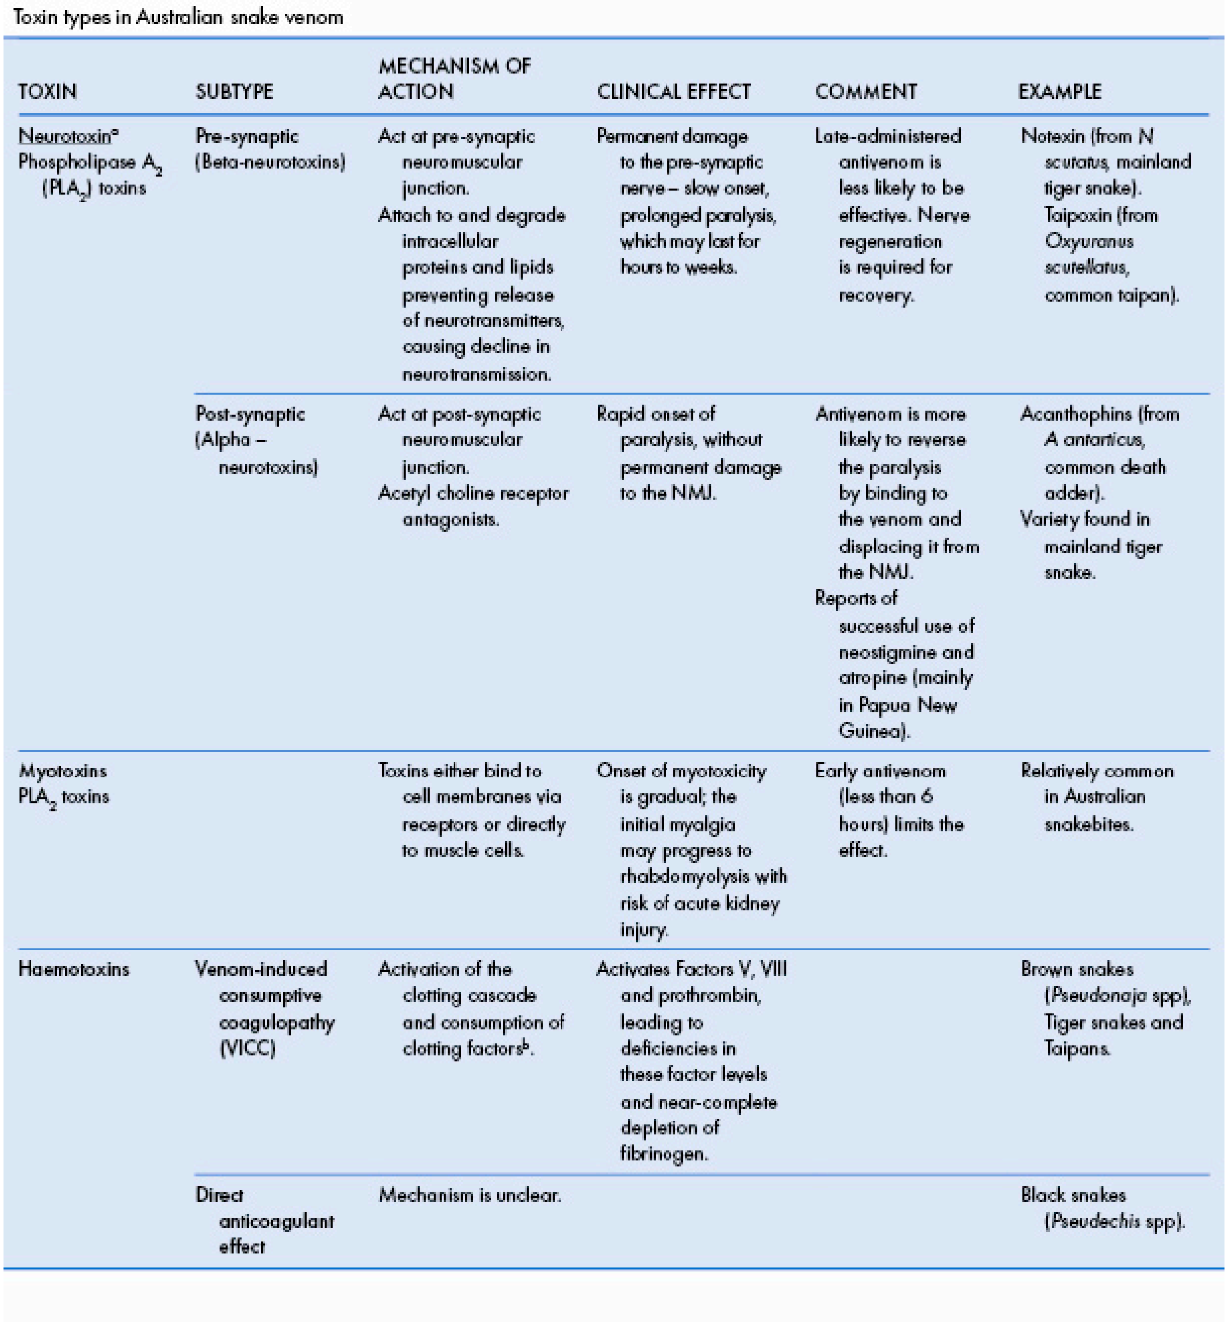
[a] Includes only deaths of patients recruited to the Australian Snakebite Project (ASP) (i.e. excludes cases in National Coronial Information System not concerning patients recruited to the ASP). Two confirmed bites by whip snakes (*Demansia* spp.) and one by an ornamental snake (*Denisonia maculata*) with envenoming are not included in the table.

AC , anticoagulant coagulopathy; *MAHA* , microangiopathic haemolytic anaemia; *NSSS* , non-specific systemic symptoms; *VICC* , venom-induced consumption coagulopathy (complete or partial).

From Johnston CI, Ryan NM, Page CB, et al. The Australian Snakebite Project, 2005–2015 (ASP-20). *Med J Aust* . 2017;207(3):119–125.

Three different toxin types are found in Australian snakes – neurotoxins, myotoxins and haemotoxins – these are summarised in Table 106.2 .

Table 106.2



Toxin types in Australian snake venom

TOXIN	SUBTYPE	MECHANISM OF ACTION	CLINICAL EFFECT	COMMENT	EXAMPLE
Neurotoxin[a] Phospholipase A_2 (PLA_2) toxins	Pre-synaptic (Beta-neurotoxins)	Act at pre-synaptic neuromuscular junction. Attach to and degrade intracellular proteins and lipids preventing release of neurotransmitters, causing decline in neurotransmission.	Permanent damage to the pre-synaptic nerve – slow onset, prolonged paralysis, which may last for hours to weeks.	Late-administered antivenom is less likely to be effective. Nerve regeneration is required for recovery.	Notexin (from *N scutatus*, mainland tiger snake). Taipoxin (from *Oxyuranus scutellatus*, common taipan).
	Post-synaptic (Alpha – neurotoxins)	Act at post-synaptic neuromuscular junction. Acetyl choline receptor antagonists.	Rapid onset of paralysis, without permanent damage to the NMJ.	Antivenom is more likely to reverse the paralysis by binding to the venom and displacing it from the NMJ. Reports of successful use of neostigmine and atropine (mainly in Papua New Guinea).	Acanthophins (from *A antarticus*, common death adder). Variety found in mainland tiger snake.
Myotoxins PLA_2 toxins		Toxins either bind to cell membranes via receptors or directly to muscle cells.	Onset of myotoxicity is gradual; the initial myalgia may progress to rhabdomyolysis with risk of acute kidney injury.	Early antivenom (less than 6 hours) limits the effect.	Relatively common in Australian snakebites.
Haemotoxins	Venom-induced consumptive coagulopathy (VICC)	Activation of the clotting cascade and consumption of clotting factors[b].	Activates Factors V, VIII and prothrombin, leading to deficiencies in these factor levels and near-complete depletion of fibrinogen.		Brown snakes (*Pseudonaja* spp), Tiger snakes and Taipans.
	Direct anticoagulant effect	Mechanism is unclear.			Black snakes (*Pseudechis* spp).

a Venomous snakes that use neurotoxins often contain a combination of pre- and post-synaptic toxins.

[b] Venom from taipans and brown snakes contains group C prothrombin activators acting similarly to endogenous Factor Xa-Va prothrombinase complex. Tiger snake, rough scale (

tropedechis sp) and *hoplocephalus* sp venom contains group D prothrombin activators, similar to factor Xa but require the presence of human factor Va to act as a procoagulant.

Approach to a Person Bitten by a Snake

Importantly, in contrast to vipers found overseas, Australian snakes do not cause local bite site destruction or symptoms. The bite is usually painless. Often, an individual bitten by a snake may have little or no signs of a bite. [5]

The vast majority (up to 90%) of snakebites will not cause envenomation.

Resuscitation efforts should be commenced in those who present with life-threatening envenomation, where there is a risk of cardiac arrest, progressive neurotoxicity or life-threatening haemorrhage.

The approach to the patient being bitten by a snake has been standardised. The overarching aim is to recognise the envenomed patient and administer antivenom to these patients as early as possible. If on presentation a victim has clinical evidence of envenoming (such as obvious bleeding or neurotoxicity) then antivenom should be administered. The same advice exists for a patient who develops clinical signs of envenoming at any time.

It is recommended that all snake bite patients, even those with no clinical evidence of envenoming, are managed in a facility with a laboratory, facilities to administer antivenom and a clinician capable of managing both complications of envenoming (such as paralysis) and the antivenom (anaphylaxis).

First Aid for Snakebite

In Australia and Papua New Guinea (PNG), the recommended first aid for snakebites is pressure bandage immobilisation (PBI). As the venom, after subcutaneous deposition, usually travels by lymphatics or small blood vessels, the PBI retards its wider distribution.

Elasticised bandages are now recommended. Crepe bandages should not be used as they fail to maintain pressure between 45 and 55 mm Hg. [6] As most victims are bitten on a limb, the technique is to apply a bandage from above the bite site, move distally to the digits and then return up the limb. The limb is then immobilised with a splint.

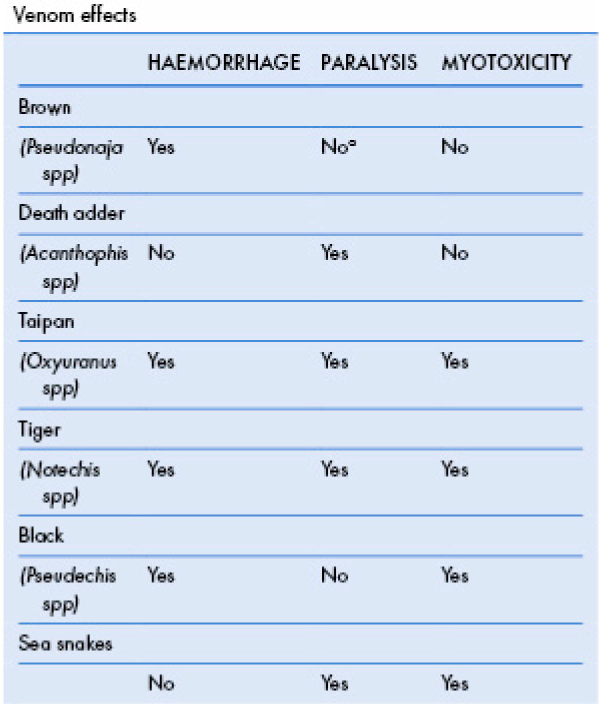
Unfortunately, PBI is often poorly performed. In a series from Darwin, only 21% of snakebite victims had appropriate PBI. [7]

Symptoms and Signs of Envenoming

Many people envenomed by a snake develop non-specific symptoms including nausea and vomiting, headache, abdominal pain and tender regional lymph nodes. Serious and potentially life-threatening initial symptoms are sudden collapse (due to either cardiac arrest or marked hypotension), paralysis and haemorrhage. These are urgent indications to administer antivenom.

A classical summary of the effects of the major genus of snakes is in Table 106.3 . However, not all patients envenomed by snakes exhibit all the clinical features. There is also venom variation in the same species of snake. For example rhabdomyolysis has been reported due to envenoming by a death adder.

Table 106.3



Venom effects

	HAEMORRHAGE	PARALYSIS	MYOTOXICITY
Brown			
(*Pseudonaja* spp)	Yes	No[a]	No
Death adder			
(*Acanthophis* spp)	No	Yes	No
Taipan			
(*Oxyuranus* spp)	Yes	Yes	Yes
Tiger			
(*Notechis* spp)	Yes	Yes	Yes
Black			
(*Pseudechis* spp)	Yes	No	Yes
Sea snakes			
	No	Yes	Yes

[a] Brown snake has a potent neurotoxin, textilotoxin. In humans this has little effect; however, in dogs and cats, this causes profound paralysis.

If there is no clinical evidence of envenoming, then laboratory investigations are required to exclude envenomation. These include a coagulation profile, blood count, renal function and creatine kinase (CK). Currently, point-of-care testing is unreliable in determining if a patient is envenomed. However, a small series of taipan envenoming from Cairns has shown that early use of rotational thromboelastometry (ROTEM) rapidly detects evidence of envenoming. [8]

If the initial bloods are normal, then the PBI can be removed, and blood tests (CK and coagulation profile) repeated 1 hour after its removal. If these are normal, then CK and coagulation profile are further repeated at 6- and 12-hours post-bite . At this stage, if the clinical exam is normal, with unremarkable bloods, the patient may be discharged in daylight hours.

If a patient develops clinical or laboratory evidence of envenoming, then antivenom is to be administered (see section below). There is no good evidence on when PBI should be removed if antivenom is administered.

One commonly used strategy is, if the patient is stable, the PBI should be removed when approximately half of the antivenom is administered. If the patient is unstable, then PBI must remain on until the patient stabilises.

Post administration of antivenom, admission for observation to detect and manage complications is needed. Repeat bloods should be performed at 6- and 12-hours post antivenom administration, then once to twice daily until sustained improvement occurs. These are performed to monitor coagulopathy, detect thrombotic microangiopathy and development of renal failure. Ongoing management of myotoxicity, neurotoxicity or thrombotic microangiopathy may be required.

Once the patient is asymptomatic with improved parameters, they can be discharged home during daylight hours with advice about serum sickness (see later).

Children

Children who are envenomed may be more difficult to diagnose if there is no known history of a snakebite. The history may be of the child becoming suddenly unwell after being outside, with either non-specific or specific symptoms of envenoming. Examination of children (such as identifying ptosis) can be challenging. Due to their lower body mass, children who are envenomed may rapidly become severely ill.

The antivenom dose is the same for children and adults.

Snake Identification

The physical identification of a snake responsible for a snakebite is often difficult and can be misleading. There are identification guides that examine snake scale patterns to correctly identify snakes; however, this is rarely, if ever, used in the clinical setting. Different Australian snakes are found in certain geographical areas, and this helps with snake identification if a person has been envenomed.

The venom detection kits (VDKs) produced by CSL (now Seqirus) had been the standard of care for evaluating snake bite victims for many years. The ASP study found a significant rate of false positive and false negative results, noting 17% of envenomed patients received an incorrect result on

VDK over a 10-year period. [4] This had led to most toxicologists not relying on VDKs to decide which antivenom to administer to an envenomed patient.

Determining Which Antivenom to Use

In Australia, Seqirus produces monovalent snake antivenom for black, brown, tiger, taipan, death adder and sea snakes, as well as polyvalent antivenom. Polyvalent antivenom contains antivenom for the land snakes only. Recent work has shown that the monovalent antivenom actually contains other snake antivenom due to the rotation of the horses to produce antivenom (i.e. it is not purely monovalent). However, the monovalent antivenom guarantees that the dose of the specified antivenom will neutralise the average venom yield for the specified venom type.

As there are specific regions where certain snakes are found, the decision on which antivenom to use is based around the geographical region where the person was bitten, the clinical findings and the laboratory investigations. If there is any doubt, then polyvalent (~45 mL) antivenom is used.

The volume of taipan and black snake antivenom is similar to polyvalent antivenom, and given these snakes are found in tropical Australia, it has been proposed that polyvalent antivenom be the antivenom of choice for this region. By contrast, when considering south-east and south-west Australia, those envenomed who develop venom-induced consumption coagulopathy (VICC) should receive tiger and brown snake antivenom. Tasmania only has snakes of the tiger snake group, so only tiger snake antivenom is recommended in this state.

Antivenom

Dose

It has been challenging to determine the optimal antivenom dose required.

Data from the ASP observational studies led to the recommendation of one ampoule of antivenom as a standard dose in both adult and paediatric settings, which is at times less than the dose recommended by the manufacturer. ASP data had shown that a reduction in dose to 1 ampoule had no adverse consequences; and venom levels were cleared with one ampoule of antivenom.[4,5]

Critics of the ASP guideline argue that although 1000 U of antivenom neutralises 10 mg of venom, venom yields from snakes can vary and larger doses of venom may be injected with multiple bites, large snakes or where the snake is forcibly detached, hence the reduced dose may leave no margin for error. The accuracy of the venom enzyme immunoassay used in the ASP studies and which toxins were detected (as venom is made up of many compounds) has also been questioned.[9,10]

For the clinician at the bedside, while one ampoule may be appropriate, it is important to be aware of the differing views and if there are concerns about the severity of the envenoming, multiple strikes or a bite by a large snake, patients may require further antivenom. Consultation with a clinical toxicologist is strongly recommended.

The recommendations currently are provided in Table 106.4 .[10]

Table 106.4

Antivenom Recommendation

Snake	ASP Study	Seqirus
Brown	One brown ampoule	One or two ampoules
Tiger	One tiger ampoule	Two [a] ampoules
Taipan	One taipan ampoule	One ampoule (up to 3 for severe envenoming)
Death adder	One death adder ampoule	One ampoule
Black mulga	One black ampoule	One ampoule
Black–red and blue bellied	One tiger ampoule	One ampoule
Sea snake	One sea snake ampoule	One ampoule (3–4 for severe envenoming)

[a] For Tasmanian tiger snakes: 2 ampoules. For Chappell Island tiger snakes: at least 4 ampoules.

Premedication

Premedication is no longer recommended for the administration of Australian antivenom.

Administration

Antivenom should be administered intravenously diluted 1 in 10 with a crystalloid solution over 30 minutes. If the patient is in cardiac arrest, rapid injection of the antivenom is recommended. For children, the same dilution is recommended; however, for small children diluting the antivenom into a 10 mL/kg solution dose is advised.

Adverse reactions

The two major adverse reactions observed with antivenom are anaphylaxis and serum sickness.

1. ASP data shows that 24% of those receiving antivenom will have a hypersensitivity reaction. Of these, 5% will have a significant anaphylactic reaction.[4] Management is along standard guidelines for anaphylaxis, with cessation of the antivenom until the anaphylaxis is under control. The antivenom should then be recommenced at a lower rate; however, further doses of adrenaline or an adrenaline infusion may be required.
2. Serum sickness may develop 5–10 days post antivenom and is a type III hypersensitivity reaction. The ASP study reported that 29% of patients who received antivenom developed serum sickness.[11] This usually presents as a flu-like illness, with malaise, joint and muscle pain, and a macular popular rash. There is no definitive evidence on when a short course of oral steroids should be used in the management of serum sickness. A pragmatic approach is to prescribe steroids which the patient may take if the symptoms became distressing.

Complications of Envenoming

1. **Thrombotic microangiopathy (TMA)**

    In Australian snakebites, TMA complicates 12% of envenomed patients who develop VICC, often occurring one to two days post envenoming. It is diagnosed by the presence of microangiopathic haemolytic anaemia (drop in haemoglobin and presence of schistocytes on peripheral blood film) and thrombocytopaenia ($<150 \times 10^9$/L or a drop by 25%). In the ASP series, TMA was more common in older patients (53 vs. 41

years); and 94% developed acute kidney injury (AKI) with 34% requiring renal replacement therapy (RRT). [12] Of those needing dialysis, 52% had ongoing chronic kidney disease (stage 3). Plasma exchange does not appear to be beneficial for TMA.

2. **Renal failure**

   While no nephrotoxin has yet been identified in Australian snake venom, some envenomed patients do develop AKI that may require RRT. This occurs more commonly in patients with VICC, who have very high d dimer levels (>4 mg/L with a median 20 mg/L), have marked rhabdomyolysis or develop TMA. Some develop anuric renal failure almost immediately, suggesting a possible direct effect of activated clotting on renal perfusion, whereas onset is delayed in others.

   Nearly all patients developing renal failure will have improvements in time, although other comorbidities may affect outcomes. Those with TMA needing haemodialysis appear to have ongoing significant renal disease.

3. **Haemorrhage**

   Catastrophic haemorrhage is a particular risk in those who develop VICC or incoagulable blood. Haemorrhage can occur spontaneously or with minimal trauma and can occur many hours after envenoming and receiving antivenom.

   Management of haemorrhage involves direct pressure where able, correcting the coagulopathy with clotting factors and replacing blood loss.

   One randomised controlled study examined if the early administration of 4 units of fresh frozen plasma (FFP) to envenomed patients with VICC would rapidly correct the coagulopathy. [13] It found that if FFP was given within 6–8 hours of the bite, the coagulopathy took longer to correct. However, if FFP was given 4 hours after the antivenom, the correction of the coagulopathy was quicker (16.5 vs. 31 hours). As this made no difference to discharge time, routine FFP is yet to be recommended.

It is unclear if using viscoelastic haemostatic assays to direct factor replacement is helpful but may be warranted in life-threatening haemorrhage.

4. **Neurotoxicity**

   This can occur with envenoming due to tiger, taipan and death adders snakes. The major threat to life is respiratory paralysis. Early antivenom is likely to lessen the severity of paralysis; however, close observation of any patient with any signs of neurotoxicity is warranted to detect any deterioration in condition. Ptosis and diplopia are early but subtle signs that should be carefully looked for. Patients envenomed with significant neurotoxicity and delayed antivenom administration may have prolonged paralysis requiring mechanical ventilation.

   Management is purely supportive. There are reports of death adder neurotoxicity improving with the use of neostigmine and atropine, which may be an option as a temporising measure in remote areas with limited resources.

5. **Rhabdomyolysis**

   Rhabdomyolysis can occur with envenomation by tiger group, taipan, black and small-eyed snakes. This is usually a gradual process evolving over many hours. Early antivenom is thought to lessen the severity of the rhabdomyolysis. Management is supportive (see chapter on management of rhabdomyolysis).

Snakebite Infections

This is extremely rare in Australian snakebite cases and antibiotics are not routinely recommended.[14] The risk of acquiring tetanus following snakebite is low as snakes do not generally harbour Clostridium tetani in their mouths; however, there have been case reports in non-Australian snake bites, especially in those which cause local tissue injury or necrosis, so it is advisable to ensure tetanus prophylaxis is up to date.[15]

Non-Australian Snakebite

People bitten by snakes outside Australia are a challenging management problem. Victims are often in rural areas with limited access to healthcare and antivenom.[16,17] Unlike Australian snakes, many envenoming syndromes cause local tissue injury as well as neurotoxicity, coagulopathy and/or rhabdomyolysis. Other more unusual presentations include anaphylaxis, hypovolaemia due to bleeding or extravasation of fluids into bitten limbs, hyponatraemia, fasciculations, renal failure and autonomic neurotoxicity.[15,16,18]

First aid is the immobilisation of the victim.[15,18] PBI is not recommended for envenomation by snakes not native to Australia or PNG. Initial management involves looking for and treating initial life threats (such as respiratory paralysis and haemorrhage). Other initial treatments include pain relief, antibiotics if a bite site is necrotic, contaminated or incised and management of local limb injury.

Diagnosis can be difficult due to limited access to laboratories and is often made clinically and using simple blood tests, such as a 20-minute whole blood clotting test (20 WBCT).

Clinical evidence of envenomation may occur due to haemotoxic, neurotoxic or cytotoxic effects (the latter evidenced by significant pain, progressive oedema or signs of tissue destruction).[19] Envenomed patients should be treated with antivenom; however, in many low-resource settings antivenom may be unreliable, unavailable, or untested. The requirement for a functional cold chain may limit the effectiveness of the antivenom. Doses are often unclear due to the lack of any formal studies, and WHO publishes recommended doses,[15,18] however, local advice is always recommended to determine both the appropriate type and dose of antivenom. While early antivenom administration is best for reducing morbidity and mortality, if there is a delay in accessing antivenom it may still be of benefit to the symptomatic patient even hours to days after the snakebite. [19] Rates of anaphylaxis are much higher when administering antivenom.

Due to the local cytotoxic nature of some of the venoms, necrotic areas may need to be amputated, and long-term disability, including chronic ulceration, osteomyelitis and arthritis may occur.

Spitting cobras (found in Africa and Asia) have the ability to intentionally shoot venom directly from their fangs. This may cause ocular envenomation (venom ophthalmia) if venom enters the eyes (characterised by lacrimation, burning and blurred vision). Ocular exposure alone without signs of systemic envenomation may be managed with local irrigation alone without antivenom. [19]

Hymenopteran Insects (Bees, Ants and Wasps)

Anaphylactic reactions to hymenopteran insect stings (bees, ants and wasps) are collectively the major cause of death from envenomation in Australia, though the annual mortality from snakebites is similar. Hymenopteran stings caused an annual average of 1200 hospital admissions per year and accounted for 32 deaths (2–3/annum, 0.11/million population per year) in Australia from 2000 to 2013. [20] The main culprit is the common European honeybee (*Apis mellifera*), though Jumper and bull ants (*Myrmecia* spp.) are also important. Numerous allergens are present in the venom of hymenopterans. [21] Refer to Chapter 109 for treatment of anaphylaxis.

Arachnids (Spiders, Scorpions and Ticks)

Although several thousand species of spiders exist in Australia, funnel-web spiders (genera *Atrax* and *Hadronyche*) and the redback spider (*Latrodectus hasselti*) are notable for causing cause significant systemic illness. While all spiders have venom, relatively few cause pain and inflammatory signs at the bite site or even minor systemic effects in humans.[22] Of note, in Australia, ‘necrotic arachnidism’ attributed to white-tailed spiders (*Lampona* species) has been debunked and causes other than a spider bite should be sought for ulcerated skin lesions.[23] Similarly, scorpion stings in Australia tend to be limited to local pain, paraesthesia and occasional non-specific self-resolving systemic symptoms.[24] Australian scorpions (*Bothriuridae*, *Buthidae* and *Urodacidae*) are not life-threatening. Treatment is focused on symptomatic relief with analgesics, and PBI is not indicated. The other arachnid with a notable envenomation syndrome is the Australian Paralysis Tick, discussed later.

Funnel-Web Spiders

At least 40 species of funnel-web spider inhabit the east coast of Australia from Queensland to South Australia and Tasmania but only species from New South Wales and southern Queensland have caused significant illness and death.[25], [26] Funnel-web spiders are large, dark-coloured and aggressive. They may be confused with other less medically significant species such as trap door spiders (Idiopidae and Nemesidae) and mouse spiders (Actinopididae), so all encounters with a ‘big black spider’ should be taken seriously in the funnel-web spider geographic distribution. A systematic review involving 138 cases identified 77 cases of severe envenomation with 13 deaths, but none occurred after the introduction of antivenom in 1981, and the vast majority (97%) responded to antivenom therapy.[27] All deaths were attributed to the Sydney funnel-web spider (*Atrax robustus*), which inhabits an area within an approximate 160 km radius of Sydney. It may enter houses and seek shelter among clothes or bedding, giving a painful bite when encountered. Unusually for spiders, it is the male funnel-web spider that has more potent venom and is primarily responsible for envenomation. Apart from *A. robustus*, life-threatening envenomation has been also caused by various *Hadronyche* species.

The venoms of funnel-web spiders contain hundreds of protein toxins.[26] A family of δ-hexatoxins bind to neurotoxin receptor site 3 and exert their effect by slowing inactivation of vertebrate and insect tetrodotoxin-sensitive sodium channels. This action results in the massive release of neurotransmitters including acetylcholine at neuromuscular junctions and within the autonomic nervous system, as well as catecholamines that may induce acute cardiac failure (resembling Takotsubo cardiomyopathy). [28] The venoms also contain numerous toxins that attack other ion channels in insects but not in humans.

Bites do not always result in envenomation, but envenomation may be rapidly fatal. Local pain is typically severe and fang marks often visible. Local swelling and erythema are absent. Envenomation can progress rapidly, and if systemic features develop, they become apparent within about two hours. [27] Early non-specific features include nausea, vomiting, headache and abdominal pain. Autonomic features include sweating, salivation, piloerection and lacrimation. Cardiovascular symptoms such as hypertension, dysrhythmias and vasoconstriction can also develop. Life-threatening features are usually heralded by the appearance of muscle fasciculation at the bite site, which quickly involves distant muscle groups and paraesthesiae may occur. The victim may lapse into a coma, develop central hypoventilation and have difficulty maintaining an airway free of secretions. Finally, respiratory failure, pulmonary oedema and severe hypotension culminate in death. In severe cases, children have died within 15 to 90 minutes of envenomation. [26]

Treatment of envenomation consists of the early application of PBI, intravenous administration of antivenom, and intensive supportive care, which may include airway support, mechanical ventilation and haemodynamic support. The antivenom is effective against envenomation by all funnel-web spiders (as well as the mouse spider). Urgent administration of antivenom is required if there are any clinical features of systemic envenoming, as they are typically sudden in onset and may rapidly progress. Often 2 ampoules are sufficient (see Table 106.5 for dosing), though, in 75 victims requiring antivenom, the median dose administered was 3 ampoules with a range of 1–17. [27] Furthermore, not all toxin effects (e.g. cardiomyopathy) may respond to antivenom therapy regardless of whether additional doses are given. [29]

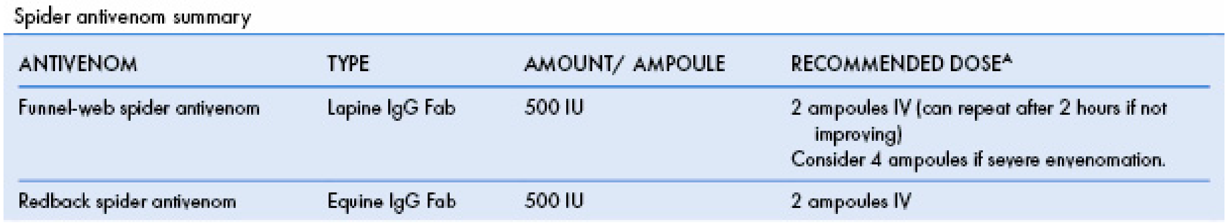
Redback Spider

Redback spider bite is probably the most common medically relevant envenomation in Australia. *L. hasselti* , is found outdoors in household gardens in suburban and rural areas throughout Australia. Related species with similar envenomation effects ('latrodectism') occur in other parts of the world, including the katipo spider (*L. katipo*) in New Zealand. The venom of *Lactrodectus* species contains multiple toxins, including alpha-latrotoxin.[26] This protein interacts with pre-synaptic receptors (such as neurexins and lactrophilins) and forms non-selective pores promoting the cytosolic entry of calcium that results in widespread exocytosis of neurotransmitters (e.g. acetylcholine at motor endplates and catecholamines). Envenomation is not life threatening but can cause severe systemic illness.

The adult female is primarily responsible for envenomation and has a 1 cm body length with a distinct red dorsal stripe over its abdomen.[26] The bite may feel like a pinprick or may be painless initially, and is often not visible.[25,26,30] Over the next minutes to several hours, severe local pain develops and may extend proximally from a bitten limb or generalise involving the abdomen, chest and back. Local erythema may occur but is mild at most. Piloerection and sweating are common and together with progressive local pain are an almost pathognomonic triad for lactrodectism. Systemic features may develop, including non-specific features such as headache, lethargy, dysphoria, nausea and vomiting, as well as autonomic features such as profuse sweating (sometimes in bizarre distributions such as bilaterally below the knees), tachycardia and hypertension. Other presentations include priapism, as a mimic of other life-threatening painful conditions (such as myocardial infarction, aortic dissection and appendicitis), or generalised distress and irritability in infants. Symptoms of lactrodectism may last hours to days but rarely persist longer than 5–7 days. No deaths solely attributed to redback spider bites are reported.

The mainstay of management is reassurance and provision of analgesia. Ice packs can be used as first aid, and commonly used initial analgesics are paracetamol and ibuprofen. Opiates such as oxycodone are indicated if pain is not adequately controlled, progressing to parenteral analgesia if required. Redback spider antivenom can be considered in discussion with a clinical toxicologist in refractory cases. However, the use of antivenom is controversial due to research questioning its clinical effectiveness (Table 106.5) . [31, 32] If used, it should be restricted to cases where the diagnosis is certain, symptoms are refractory to analgesic control, and the patient is aware of the risks. Risks of redback antivenom include allergic reactions (<5% risk of occurrence, with anaphylaxis rare) and serum sickness (<10% risk of occurrence, consisting of fever, rash, arthralgia and myalgia that self-resolves within 14 days). [25]

Table 106.5



Spider antivenom summary

ANTIVENOM	TYPE	AMOUNT/ AMPOULE	RECOMMENDED DOSE[a]
Funnel-web spider antivenom	Lapine IgG Fab	500 IU	2 ampoules IV (can repeat after 2 hours if not improving) Consider 4 ampoules if severe envenomation.
Redback spider antivenom	Equine IgG Fab	500 IU	2 ampoules IV

[a] The dose of antivenom is usually administered diluted in 100 mL normal saline (or 10 mL/kg in children) and administered intravenously over 20 minutes. In cardiac arrest administration of undiluted antivenom can be considered.

Australian Paralysis Tick

The Ixodes tick (*I. holocyclus, I. hirsti* and *I. cornuatus*) injects holocyclotoxins that cause flaccid paralysis (with sensory sparing) 3–5 days after feeding on humans. [33] The ticks inhabit the east coast of Australia from far north Queensland to Victoria and Tasmania, especially in the peak season of spring-summer. The diagnosis should be considered in any young children with drowsiness, difficulty walking or weakness in these regions. The onset of ascending paralysis resembles that of Guillain–Barré syndrome, but cranial nerve palsies (e.g. ophthalmoplegia) are often present and the identification of one or more ticks is diagnostic. The ticks are usually found in the scalp but may be located anywhere on the skin including relatively hidden locations such as the auditory canal, natal cleft and perineum. Prompt removal of tick(s) is necessary: carefully grasp the tick as close to the skin as possible to ensure removal of all the mouth parts while applying gentle traction. Envenomed patients also require a period of observation as late-onset paralysis can occur even 48 hours after tick removal. No antivenom is available and mechanical ventilation may be required for up to a week, with further recovery occurring over several weeks.

Marine Envenomation

While more than 10,000 species of jellyfish exist, few are dangerous to humans, with only 100 species worldwide being responsible for human envenomation. [34] Most species cause no systemic symptoms, with only localised pain and skin reaction at the site of tentacle contact. [35] Rarely jellyfish stings have been associated with anaphylaxis [36] and case reports of Guillain–Barré syndrome exist. [37]

However, two of the most dangerous jellyfish, the Australian box jellyfish (*Chironex fleckeri*) and *Carukia barnesi* , a Cubozoan jellyfish species that can cause Irukandji syndrome, are found in Australian waters.

Australian Box Jellyfish

Chironex fleckeri is the major Australian box jellyfish (Class *Cubozoa*) found in tropical Australian waters [38] and likely the wider Indo-Pacific region. [39] It is the most dangerous jellyfish in the world, with one of the most lethal and rapidly active venoms known. It is also the only jellyfish for which an antivenom is available. [40] There have been at least 80 documented fatal stings within Australian waters with most deaths occurring within minutes of the sting due to cardiorespiratory arrest. [38], [39] The greatest risk of envenomation is in northern Australian waters from October to May, [39] although deaths have occurred in all months except July. [41]

It is a multi-tentacled jellyfish with a box-shaped bell up to 35 cm in diameter and tentacles of up to 3 metres in length which are covered with millions of stinging nematocysts. [40] The nematocysts discharge toxins, through a penetrating thread, into the skin of any creature it encounters. [40] Stings usually occur in shallow water, with the box jellyfish often not seen until the tentacles have made contact. [40] The severity of envenomation is related to the size of the jellyfish (bell diameter greater than 15 cm associated with increased severity) and extent of tentacle contact, with death being probable if the total length of wheels from tentacles is more than 6–7 metres. [40] The exact mechanism of action of the *C. fleckeri* venom is unknown, but may involve calcium influx due to toxin-induced pore formation. [40]

Stings from contact with the tentacle's nematocysts cause severe pain at the site which can persist for days, despite removal of the tentacles. Linear wheals occur, classically with a pattern of transverse bars ('frosted ladder patterns') matching the bands of nematocysts on the tentacles, followed by oedema, erythema and vesiculation. [40] This is then followed by full-thickness necrosis and permanent scarring. Systemic effects of envenomation include hypotension, vasospasm, cardiac arrhythmias and cardiac arrest. [39] Loss of consciousness occurs within seconds of envenomation in severe cases. [40] The mechanism of death is not known with certainty but is likely due to a combination of cardiovascular (severe hypotension, cardiac dysrhythmias and pulmonary hypertension) and respiratory effects (apnoea). [40] Diagnosis is based on clinical features and can be confirmed by applying transparent sticky tape to the skin site then examining microscopically on a glass slide, or alternatively by examining skin scrapings. [40]

Management of Envenomation

Prevention is crucial; ideally, water should not be entered when jellyfish are present, otherwise, protective clothing 'stinger suits' or only swimming in dedicated stinger enclosures are recommended. Most stings occur in water of less than 1 metre depth, with many occurring on entering or standing in shallow water. [38]

Immediate first aid involves removing the victim from the water to prevent drowning or further stings and commencing CPR if required. Prolonged CPR may be necessary and should be continued where possible during transportation to the hospital. Extracorporeal life support may be considered, although the majority of envenomations occur in geographical locations where this is not available.

Only about 1% of tentacles discharge on initial contact, so clinging tentacles should be de-activated or removed if possible. [35] If available, vinegar (not alcohol) should be poured on adherent tentacles to de-activate them (removal is not immediately necessary once de-activated). [40] Despite urban legends, the application of urine for this purpose is not beneficial! Live tentacles (not treated with vinegar) should be treated with caution, although if only touched with fingertips they are unlikely to cause more than a prickling sensation. [40] The use of PBI is controversial and is currently not recommended unless vinegar has already been applied as it may induce the discharge of more venom from partially discharged nematocytes. [40,42] The administration of ice packs after vinegar usually reduces pain in mild stings. [40] Hot water immersion has no benefit over ice packs. [43]

While some controversy exists regarding the evidence of antivenom effectiveness, [44] antivenom should be administered as soon as possible in unwell patients once immediate first aid occurs. Indications for administration are haemodynamic or respiratory instability, including cardiorespiratory arrest, loss of consciousness and difficulty talking or swallowing. Expert consensus is to dose 3 ampoules intravenously (preferably via infusion with a dilution of 1 in 10), this dose may need to be repeated. If intravenous access is not available, antivenom may be administered intramuscularly, preferably remote to the site of envenomation. [40] There is a risk of serum sickness which can be managed with oral steroids if required. There is no evidence for the use of calcium channel blockers in envenomation despite the potential mechanism of venom action. Magnesium may theoretically improve antivenom efficiency, [40] although should not delay its use. Topical corticosteroids or oral antihistamines or steroids may reduce the swelling and itchiness of skin lesions. [40] Ongoing critical care management following the administration of antivenom is otherwise supportive.

Irukandji Syndrome

Irukandji syndrome is an extremely painful generalised syndrome, usually occurring 30 minutes after envenomation by certain jellyfish, due to a significant catecholamine surge and sympathetic response. It is named after a local Aboriginal tribe from the Cairns region where the syndrome was first recognised. [40] Although the *Carukia barnesi* was the first jellyfish identified as causing Irukandji syndrome, several similar species can also cause the syndrome. It occurs throughout northern Australian waters, including Queensland, Western Australia and the Northern Territory, predominantly during the summer months, although has also occurred in other tropical regions in the world.

Carukia barnesi is very small compared with other jellyfish, with a square bell 12 mm wide and 4 tentacles of varying lengths. Due to its small size, it can often pass through ‘stinger nets’. It is almost completely transparent in water and has clumps of nematocytes both on the bell and tentacles. [40] The venom acts as a potent neuronal sodium channel modulator, inducing high levels of catecholamines.

The initial sting is often either not noticed or causes minimal discomfort to the victim and may cause an area of mild erythema with surrounding papules or ‘goose pimples’ [40] in diameter larger than the actual bell. Usually 30 minutes after the sting (but ranging from 5 minutes up to 2 hours) generalised symptoms occur due to a surge in catecholamine release due to the venom. Generalised symptoms include severe abdominal and back pain, muscle cramps, headache, nausea, vomiting, profuse sweating, agitation and restlessness, usually associated with tachycardia and hypertension. [34] Priapism has also been reported. [45] The syndrome is often associated with a feeling of ‘impending doom’. [34] Two deaths have occurred from intracerebral haemorrhage (likely hypertension-induced) and stress-induced cardiomyopathy and cardiac failure have occurred. [46] The mechanism of cardiac failure may be secondary to hypertension or via direct cardiac depression through direct toxicity of catecholamines or via pore formation on cardiomyocytes disturbing cellular function [34] permitting toxins to enter.

Management of Envenomation

There is no definitive evidence that vinegar inactivates undischarged nematocytes, as such vinegar is not routinely administered, and no antivenom exists.

Pain management is the most important aspect in mild to moderate cases with many patients requiring intravenous opiates in repeat doses.[40] Intravenous magnesium (10 mmol loading ± infusion) has been shown to be effective in some studies, but not in others.[47,48] When effective it immediately reduces pain and the hyperadrenergic features of the syndrome likely via reduction of vascular resistance and adrenergic suppression, although its mechanism of analgesia is unclear.[40] Generally, a trial of magnesium in Irukandji syndrome is recommended, but not continued if there is a lack of response.

Clonidine (alpha-2 agonist) has been used to reduce intravenous opiate requirements, with a retrospective study showing those who received clonidine requiring less intravenous opiates than those who did not.[46]

Severe hypertension can necessitate the use of anti-hypertensives. Titratable nitrates (e.g. glyceryl trinitrate) are often preferred. If unresponsive to this intravenous phentolamine or labetalol infusions have been used.

Management of cardiac failure is supportive and may require diuretics, vasodilators, inotropes and non-invasive or invasive ventilation. Troponin should be measured, and echocardiography performed if indicated clinically to assess for heart failure.

Blue-Ringed Octopus

The blue-ringed octopus (*Hapalochlaena sp*) is a small octopus located in shallow coastal waters and rockpools around Australia, the Indian subcontinent and the Indo-Pacific region. Its saliva contains a potent sodium channel-blocking neurotoxin called tetrodotoxin. This is injected by a usually painless bite via its beak if it feels threatened, which is signalled by its rings turning iridescent blue. Symptom onset occurs within minutes. Early signs include vomiting, ptosis, blurred vision and difficulty swallowing. It causes rapidly progressive symmetrical descending flaccid paralysis, with fixed dilated pupils but no impairment of consciousness. Respiratory muscle paralysis can lead to hypoxic cardiorespiratory arrest. There have been at least 3 deaths worldwide.[49]

No antivenom is available. Management includes PBI and supportive care including sedation and mechanical ventilation. Paralysis resolves spontaneously within 24 hours.

Stinging Fish – Stonefish

Stonefish (*Synanceia* spp) are the world's most venomous fish species with dorsal spines that contain venom which is injected in response to external pressure. They are generally found in tropical and temperate areas of the Indo-Pacific, including northern Australia where they are usually located partially buried in the substrate of estuaries and sheltered bays. [50] The venom contains pre- and post-synaptic neurotoxins, haemolytic, vascular permeability and tissue necrosis factors. Severe immediate pain at the site is characteristic with localised swelling, bruising and spinal remnants often remaining in the wound. Systemic envenomation is rare, however, may include nausea, vomiting, dyspnoea and rarely cardiovascular collapse. No deaths have been reported in Australia. Management includes analgesia, immersion of limbs in hot water (heat denatures some venom components) and supportive care. Regional anaesthesia can be effective; however, care must be taken if used in conjunction with hot water immersion due to the risk of burns to anaesthetised tissue. Antivenom is available and is indicated for severe pain or systemic envenomation.

Cone Snail (Shell)

The *Conus* species contains a venom-covered hook or harpoon which can cause paralysis via neuromuscular blocking effects. Human envenomation predominantly occurs during handling and deaths have occurred. Envenomation causes pain and necrosis at the envenomation site, weakness, muscle paralysis, respiratory, cardiovascular collapse and coma. No antivenom exists, and management is supportive. [51]

Blast and ballistic trauma

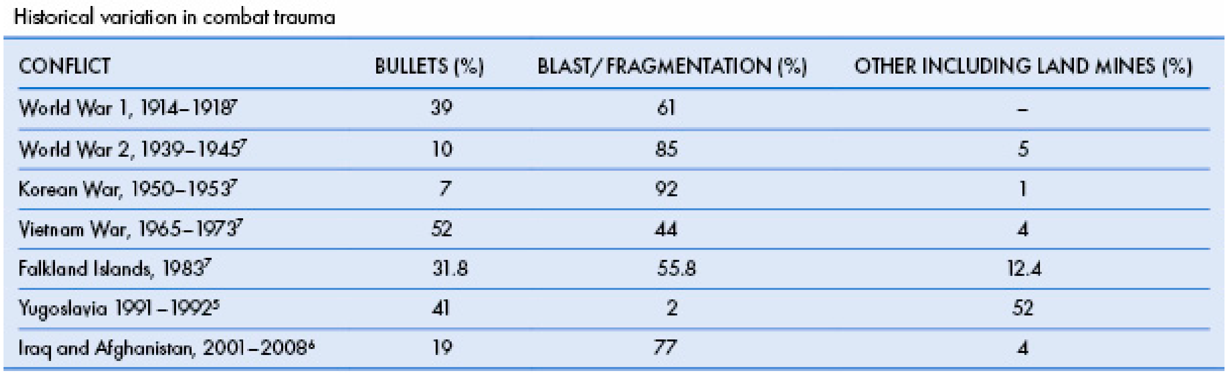
Michael Charles Reade, Tom Woolley and Elissa Mary Milford

The number of mass casualty events involving firearms (e.g. Pittsburgh synagogue shooting 2018; Christchurch mosque shooting 2019) and explosions (e.g. Brussels, 2016; Parsons Green London 2017) continues to increase. Most still occur in the developing world (e.g. 149 deaths and 186 wounded in the Mastung bombing, Pakistan, 2018) but are under-reported in Western media.[1,2] Civilian single-victim firearm attacks and accidental explosions (e.g. Beirut, 2020) are even more numerous. Principles of managing blast and ballistic trauma are not well-appreciated outside the military and humanitarian organisations,[3] developed considerably during the wars in Iraq and Afghanistan, and are being advanced further by peer-on-peer conflict in Ukraine.[4] Misunderstandings can result in counter-productive planning (e.g. pre-emptively emptying ICUs, or failing to anticipate repeated wound surgery over many weeks) and treatment (e.g. needless extensive wound debridement). This chapter will hopefully remain a curiosity for most. For the increasing minority who need to read it in detail, perhaps unexpectedly, we hope it provides useful advice.

Epidemiology of Blast and Ballistic Trauma

Different military conflicts produce characteristic wounding mechanisms, summarised in Table 107.1 .[5-7] The trend towards more head and neck wounds in recent conflicts (Table 107.2)[5,8] is attributed to better thoraco-abdominal body armour.[9] The wounded:killed ratio depends on weapon types (Table 107.3 .),[5,10] physical surroundings, protective equipment and medical support. In modern war the overall wounded:killed ratio ranges from 2:1 to 13:1, [11] over time averaging 4:1. [5-8] Historically, the proportion of combat that occurs in armoured fighting vehicles has been particularly important: armour crews have been less likely to be wounded than infantry (hence lower *population mortality*), but those that were had a much higher *case fatality rate* . Modern infantry anti-armour weapons are likely to reduce this mortality disparity. Burns are particularly common in surviving armoured warfare casualties (30% in some series) [12] but not amongst infantry wounded.

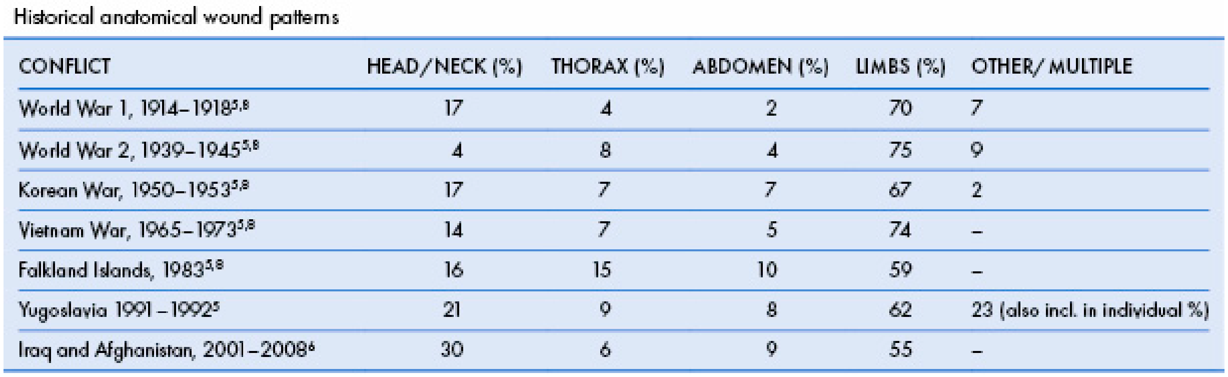
Table 107.1



Historical variation in combat trauma

CONFLICT	BULLETS (%)	BLAST/FRAGMENTATION (%)	OTHER INCLUDING LAND MINES (%)
World War 1, 1914–1918[7]	39	61	–
World War 2, 1939–1945[7]	10	85	5
Korean War, 1950–1953[7]	7	92	1
Vietnam War, 1965–1973[7]	52	44	4
Falkland Islands, 1983[7]	31.8	55.8	12.4
Yugoslavia 1991 – 1992[5]	41	2	52
Iraq and Afghanistan, 2001–2008[6]	19	77	4

Table 107.2



Historical anatomical wound patterns

CONFLICT	HEAD/NECK (%)	THORAX (%)	ABDOMEN (%)	LIMBS (%)	OTHER/MULTIPLE
World War 1, 1914–1918[5,8]	17	4	2	70	7
World War 2, 1939–1945[5,8]	4	8	4	75	9
Korean War, 1950–1953[5,8]	17	7	7	67	2
Vietnam War, 1965–1973[5,8]	14	7	5	74	–
Falkland Islands, 1983[5,8]	16	15	10	59	–
Yugoslavia 1991 – 1992[5]	21	9	8	62	23 (also incl. in individual %)
Iraq and Afghanistan, 2001–2008[6]	30	6	9	55	–

Table 107.3

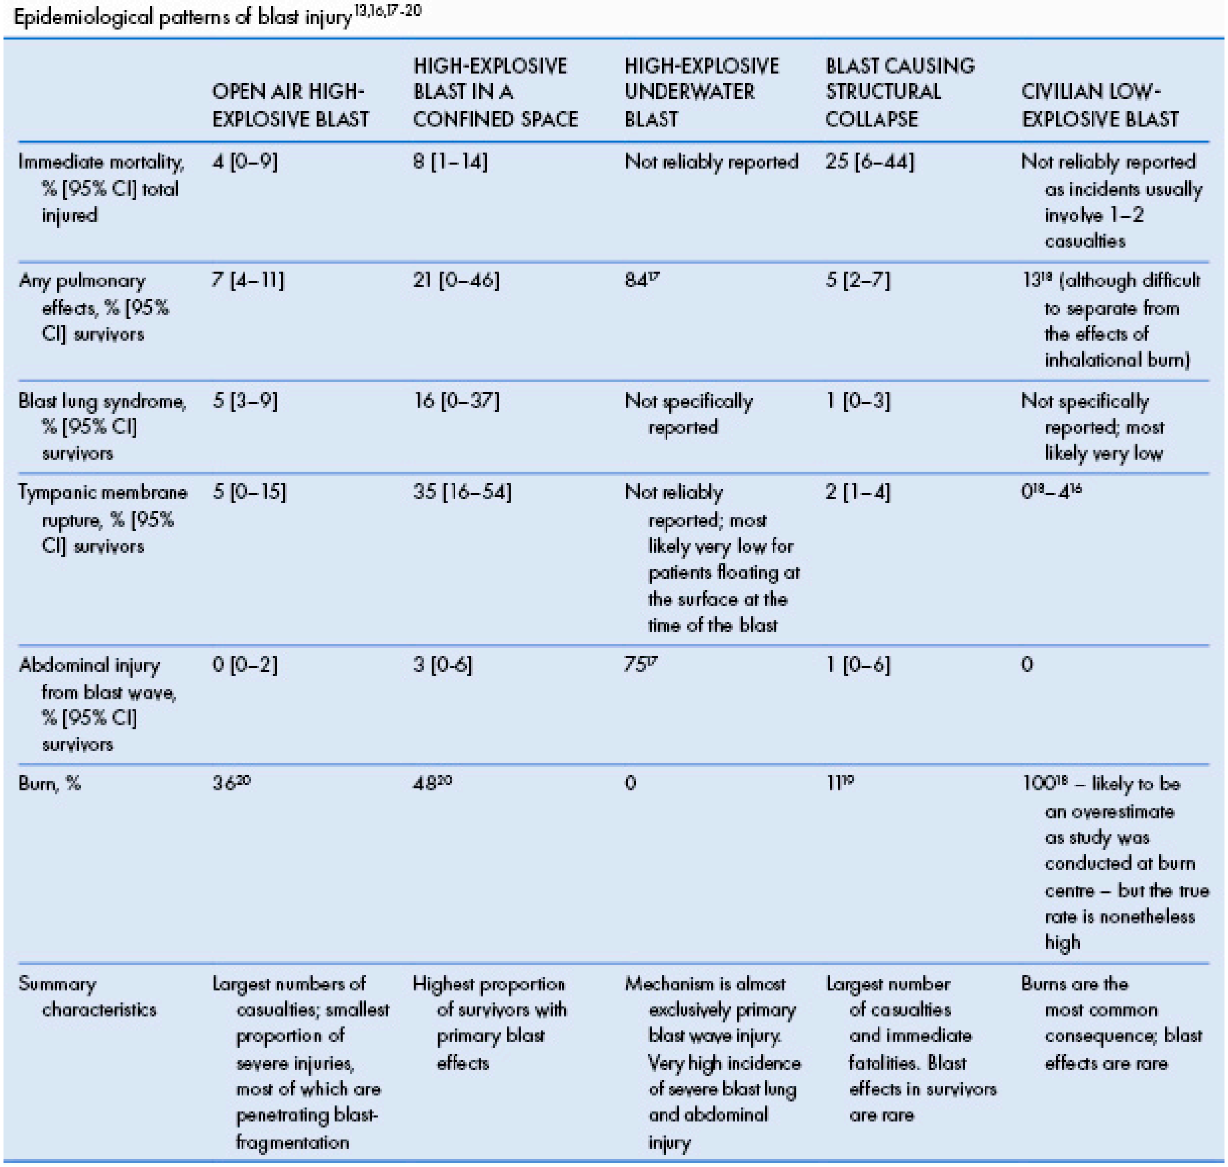
Mortality associated with different weapons systems employed in combat [5, 10]

Military rifle bullet	30%–40%
Blast	22%
Blast fragmentation – randomly formed fragments	20% artillery shells; 10% grenades
Blast fragmentation – military preformed fragments	15% artillery shells; 5% grenades

Firearms used in a civilian context are more lethal than on the battlefield, with wounded:killed ratios ranging from 0:1 to 1:3, [11] as civilian shootings occur at close range with unarmed victims who cannot escape. Higher than expected mortality in war suggests executions rather than combat deaths, and has been used as evidence of war crimes. [11]

Blast trauma conforms to one of five epidemiological patterns (Table 107.4). [13] Understanding the context of blast provides clues to clinical priorities and response planning. For example few civilian blast survivors (approximately 15%) require surgery, and even fewer (6%–13%) require intensive care. [14] Burns are common in survivors of the low-explosive blast, [15] but in high-explosive blast, the blast wave is usually fatal to victims close enough to be burnt.

Table 107.4



Epidemiological patterns of blast injury[13,16,17-20]

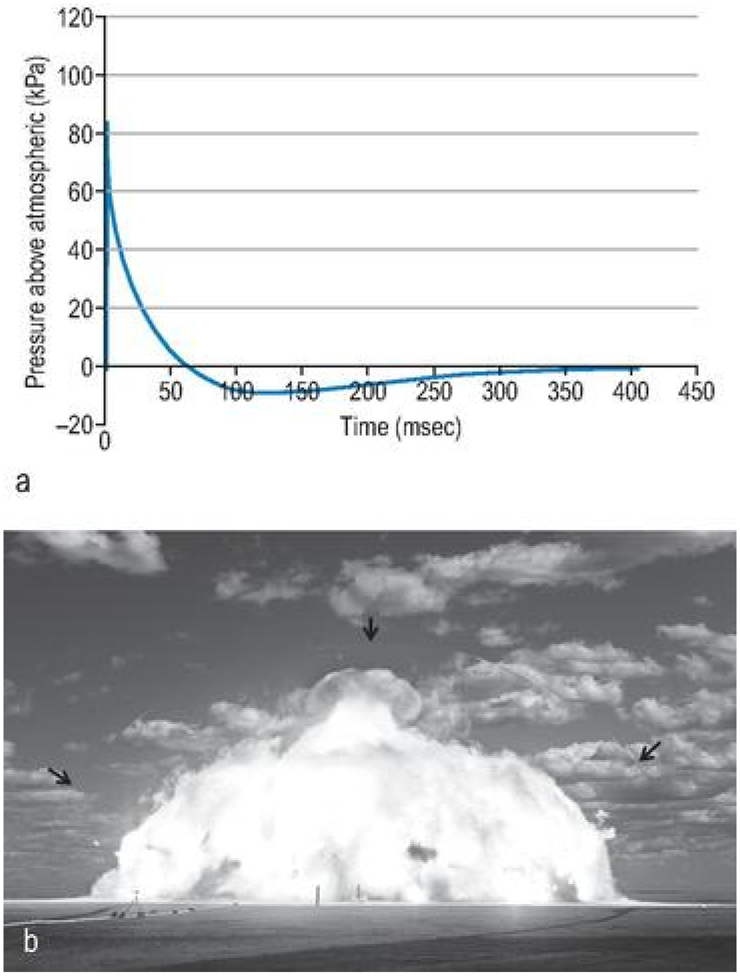
	OPEN AIR HIGH-EXPLOSIVE BLAST	HIGH-EXPLOSIVE BLAST IN A CONFINED SPACE	HIGH-EXPLOSIVE UNDERWATER BLAST	BLAST CAUSING STRUCTURAL COLLAPSE	CIVILIAN LOW-EXPLOSIVE BLAST
Immediate mortality, % [95% CI] total injured	4 [0–9]	8 [1–14]	Not reliably reported	25 [6–44]	Not reliably reported as incidents usually involve 1–2 casualties
Any pulmonary effects, % [95% CI] survivors	7 [4–11]	21 [0–46]	84[17]	5 [2–7]	13[18] (although difficult to separate from the effects of inhalational burn)
Blast lung syndrome, % [95% CI] survivors	5 [3–9]	16 [0–37]	Not specifically reported	1 [0–3]	Not specifically reported; most likely very low
Tympanic membrane rupture, % [95% CI] survivors	5 [0–15]	35 [16–54]	Not reliably reported; most likely very low for patients floating at the surface at the time of the blast	2 [1–4]	0[18]–4[16]
Abdominal injury from blast wave, % [95% CI] survivors	0 [0–2]	3 [0-6]	75[17]	1 [0–6]	0
Burn, %	36[20]	48[20]	0	11[19]	100[18] – likely to be an overestimate as study was conducted at burn centre – but the true rate is nonetheless high
Summary characteristics	Largest numbers of casualties; smallest proportion of severe injuries, most of which are penetrating blast-fragmentation	Highest proportion of survivors with primary blast effects	Mechanism is almost exclusively primary blast wave injury. Very high incidence of severe blast lung and abdominal injury	Largest number of casualties and immediate fatalities. Blast effects in survivors are rare	Burns are the most common consequence; blast effects are rare

Causes and Timing of Death in Blast and Ballistic Injury

Seventy percent of blast and ballistic trauma deaths occur due to brain injury or exsanguination within 5 minutes of wounding,[5] and almost none of these early deaths are preventable with treatment. However, most ballistic wounds are not fatal. Of US combatants who died in the Vietnam War, [8] 25% had potentially correctable surgical causes, and 12% died of infections and other complications. Improvement in hospital care has virtually eliminated the late mortality peak, [21] leaving prehospital care the main target to reduce further preventable mortality. Of preventable deaths, the most quoted paper [8] referred to US autopsies in the Vietnam War: 60% died due to extremity haemorrhage, 33% from tension pneumothorax and 6% from airway obstruction. Military personnel are trained to treat these three mechanisms. [22] These figures can skew training priorities as they report on patients who died, ignoring those who survived because simple interventions such as airway opening were performed. Further, the incidence of tension pneumothorax may be over-represented. The 33% figure appears to originate in 893 chest radiographs of patients who died prehospital in Vietnam [23] ; a problematic study which required judging the relevance of other injuries examined up to 4 days postmortem, which did not take into account prehospital thoracentesis that might have *produced* pneumothoraces, and which concluded an incidence 5 × higher than reported in World War 2. [23]

Blast Trauma

An explosion occurs when a substance undergoes a chemical or nuclear reaction that almost instantaneously transforms liquid or solid matter into its gaseous phase resulting in the release of energy in the form of a pressure wave, light, sound and heat. This chapter discusses ‘conventional’ chemical rather than nuclear explosions. *High explosives* produce a supersonic pressure wave, whilst slower-burning low explosives do not. The first force felt by an affected body is the static pressure wave, depicted in Fig. 107.1 . There is no mass movement of gas; rather pressure rapidly increases and then becomes sub-atmospheric. Energy dissipates inversely proportional to the cube of distance. Hard surfaces reflect pressure waves, increasing the transmitted force in enclosed spaces, and blast underwater has a slower rate of energy dissipation and a high propagation rate. [11] The second force felt by a body in the air is the mass movement of gases: the ‘blast wind’, which near its origin contains sufficient thermal energy to cause burns. The momentum of solid objects accelerated by the blast wind can wound well beyond the danger zone of the blast wave or wind. Blast injuries are classified as primary, secondary, tertiary, quaternary and quinary (Table 107.5 and Fig. 107.2).



The two-part illustration is labelled a and b. Part a is a graph that exhibits pressure above atmospheric level in kilopascals plotted on the vertical axis and time in milliseconds on the horizontal axis. The graph line starts steeply at around 80 kilopascals at 0 milliseconds and drops rapidly, approaching 0 kilopascals by approximately 100 milliseconds, then levelling out near atmospheric pressure. Part b is a grayscale photograph of a large explosion at ground level, forming a hemispherical white cloud with arrows pointing to the outer edges of the expanding shockwave.

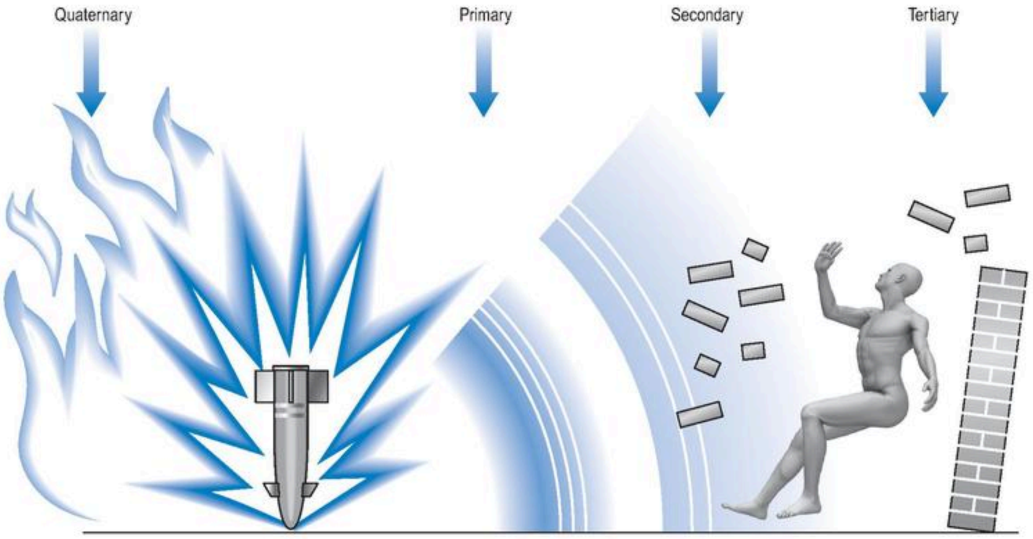
FIG. 107.1 A blast pressure (Friedlander) wave in air, with the peak overpressure shown diagrammatically in (A) visible as a change in the refractive index of air in (B). Interactions with surfaces, including the ground commonly distort this wave. In many cases, this increases the magnitude of the peak pressure at certain positions, resulting in different forces applied to casualties located similar distances from the blast origin.

Table 107.5

Mechanisms of blast injury

Type of Blast Injury	Mechanism	Effects
Primary	Static pressure wave, causing barotrauma due to overpressurisation then underpressurisation	Affects mainly air-filled organs: Tympanic membrane rupture ‘Blast lung’ Hollow viscera rupture (colon) Mild traumatic brain injury (mTBI) Eye (globe rupture, hyphaema, serous retinitis)
Secondary	Effects of projectiles propelled by the explosion	Penetrating injury Soft tissue trauma Traumatic amputation
Tertiary	Effects due to mass movement of air (‘blast wind’), either directly or by interaction with the surroundings, including collapse of buildings	Blunt and penetrating injury Bone fracture Traumatic amputation Open or closed TBI Crush injury. Entrapment
Quaternary	All other immediate effects of blast, including burns, oxygen depletion, creation of dust,	Skin and airway burns Asphyxiation

Type of Blast Injury	**Mechanism**	**Effects**
	inhalation of toxic gases (CO, cyanide)	
Quinary	Delayed hyperinflammatory response; delayed effects from bacterial or radiological exposure	Infection Organ failure



The conceptual diagram represents the four categories of blast-related effects. From left to right, under the label Quaternary, stylised flames represent thermal and chemical effects. At the centre, under Primary, a large detonation depicted by a missile and radiating spikes illustrates the blast wave impact. To the right of that, under Secondary, curved shockwave lines transition to scattered dark blocks indicating debris propelled by the explosion. Furthest right, under Tertiary, a grayscale human form is shown in mid-air, appearing to be thrown backwards by the blast into a wall of blocks.

FIG. 107.2 Mechanisms of blast injury. (Courtesy Colonel Anthony Chambers FRACS RAAMC.)

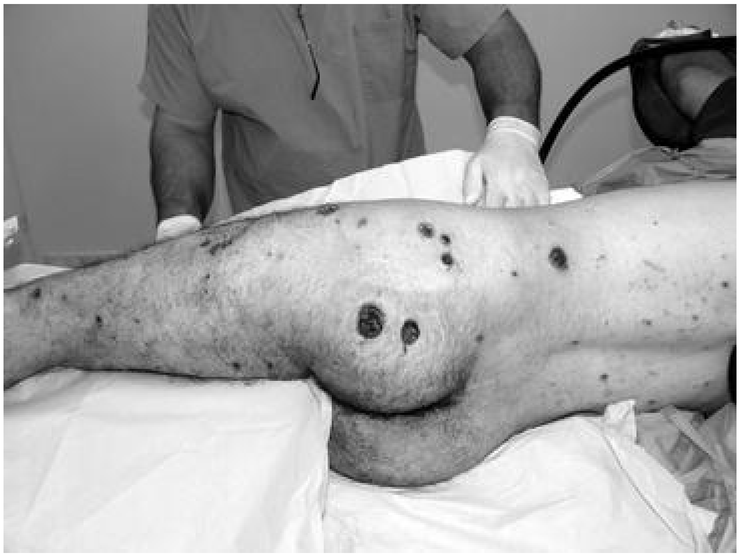
Pathophysiology of Blast Injury

Primary blast injury is caused by the blast pressure wave and is a common cause of death in military blasts, [24] but is uncommon (e.g. 7% in one series

[25]) in survivors. If the casualty is close enough to suffer a primary blast injury, secondary and tertiary effects are usually fatal. Civilian low-explosive blast almost never has sufficient energy to cause primary blast injury. [15]

Primary blast injury is caused by the alternating overpressure and underpressure of the pressure wave. Tissues are damaged by three main mechanisms that predominantly affect gas-containing organs with interfaces of different tissue density. *Spallation* , the most important mechanism, is fragmentation of the high-density tissue into the low due to the passage of the pressure wave. *Implosion* results from the rapid compression and re-expansion of air. *Shearing* is due to acceleration and deceleration causing tearing.

Secondary blast injuries are caused by debris carried up to hundreds to thousands of metres by the blast wind. Secondary injuries are more common than primary blast injuries, which usually occur within tens of metres of the blast centre. They were more than three times more common than primary blast injuries during Operation Iraqi Freedom. [26] Survivors of blast-fragmentation injuries often have many low-energy superficial wounds (‘peppering’ or ‘battle acne’: Fig. 107.3). Up to 80% of military blast casualties will have ocular trauma if not wearing eye protection [27] ; more than in civilian studies, although eye injuries in civilian urban environments from shattering glass are also common.



The photo shows a medical setting with a patient lying on a treatment table covered with sheets. The patient's left leg is fully exposed and extended laterally, revealing numerous circular lesions of varying sizes concentrated on the lateral thigh, buttock, and hip.

FIG. 107.3 'Peppering' or 'battle acne' wounds characteristic of secondary blast injury. (Courtesy Dr Daron Cunningham, Libya, 2011.)

Tertiary blast injuries occur when victims are physically propelled by the blast wind or by the collapse of surrounding structures, resulting in predominantly blunt trauma. Quaternary injuries are those that are not classified as primary, secondary or tertiary such as burns, toxic gas exposure and psychological trauma. The quinary category has been used to describe a delayed hyperinflammatory response or the delayed effects from bacterial or radiological exposure.

Presentation and Management of Blast Injury

Presentations vary depending on explosive type, proximity and orientation of the victim in relation to the blast, presence of penetrating trauma and the surrounding structures. Organ systems injured can be identified using the same systematic approach as with any polytrauma presentation.

Cardiovascular Injuries

The immediate response to blast to the chest is a unique form of cardiogenic shock characterised by vagal-mediated hypotension, bradycardia and apnoea that can be refractory to resuscitation. It may reoccur up to three hours after the blast. Thoracic compartment syndrome can develop due to mediastinal oedema or haemorrhage. Blunt cardiac injuries may also occur, and these are managed as per conventional guidelines.

Ear Injuries

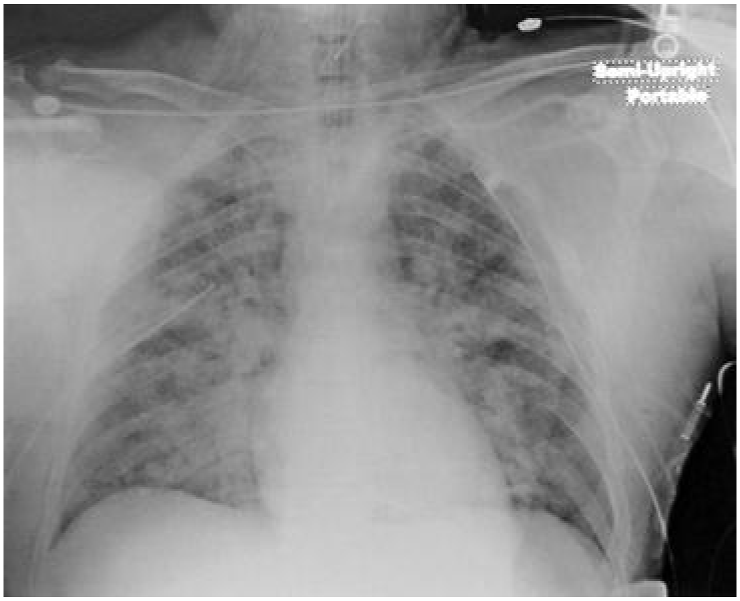
Blast especially affects gas-containing organs, of which the ear is the most sensitive. There is a high incidence (reports vary from 16% to 41%) [28], [29] of tympanic membrane (TM) rupture. TM sensitivity to blast led to recommendations it be used as an effective screen for blast injury to other organs, but this is unsupported by clinical experience. TM disruption was present in only 50% of patients with other significant blast injuries. [25] There may be membrane haemorrhage without rupture, and ossicular or cochlear damage may also occur. Head orientation to the blast is a key determinant of vulnerability. However, there is a strong association between TM rupture and loss of consciousness. [30]

TM rupture or damage to other auditory structures can cause tinnitus, pain, hearing loss and abnormal vestibular function. One-third of casualties experiencing TM rupture will have permanent hearing loss.

Blast victims with auditory or vestibular dysfunction should have specialist ear evaluation within 48 hours of injury due to the higher rates of large perforation and lower rates of spontaneous healing, and the risk of damage to middle ear structures. TM rupture is usually treated conservatively, as most heal spontaneously. About 25% require delayed surgical closure. Avoidance of additional barotrauma, noise reduction, removal of external auditory canal debris and keeping the external auditory canal dry will prevent secondary damage. Avoid ear irrigation. Consider topical antibiotics in the presence of debris or signs of infection.

Lung Injuries

Blast injury at the alveolar–capillary interface can cause air emboli, pneumothorax, lung contusion, haemothorax, alveolar haemorrhage, mediastinal air and subcutaneous emphysema. [31] As alveoli flood with fluid, cellular debris, and inflammatory cells, the result is ‘blast lung’ (Fig. 107.4), with hypoxaemia caused by ventilation–perfusion mismatch. Blast lung typically develops over 24–48 hours and takes 7–10 days to resolve. Good recovery from severe blast lung can be expected with conventional mechanical ventilation. [32] The risk of blast lung is increased by blast in a confined space and by proximity. Presentation ranges from mild hypoxaemia to frothy sputum, profound hypoxaemia and subcutaneous emphysema. A chest radiograph will distinguish pneumothorax, haemothorax or pulmonary parenchymal damage from hypoxaemia due to other causes (e.g. inhalation of toxic gases). Patchy infiltrates in a ‘batwing’ pattern on chest radiographs are classical findings in blast lung; however, these are only present in approximately 50%–90% of cases, whereas CT of the chest has a sensitivity of 100%. [33] Arterial air emboli from alveolar–pulmonary venous communications cause most early deaths. Signs of air emboli include cerebral dysfunction such as altered affect, confusion or focal neurological signs. Emboli to the coronary arteries can cause arrhythmias or ischaemia.



The semi-upright portable chest X-ray depicts the thoracic cavity. The view reveals bilateral hazy opacities throughout both lungs with reduced clarity of vascular markings. The bony structures, including the clavicles, ribs, and spine, are faintly visible, while the heart and diaphragm contours are partially obscured by the overlying opacities.

FIG. 107.4 Blast lung, showing characteristic perihilar infiltrates. CT is more sensitive than plain radiography. (Courtesy Australian Defence Force, Afghanistan, 2012.)

Recommendations for blast lung are extrapolated from those for other causes of acute respiratory distress syndrome (ARDS), despite the known differences in pathogenic mechanisms. Approximately 80% require mechanical ventilation.[34, 35] Risk of systematic air embolism increases with mechanical ventilation, suggesting minimising airway pressures and permissive hypercapnia may be useful. A high inspired fraction of oxygen in the first 24 hours may be beneficial by increasing the rate of gas emboli dissolution.[36] Nitric oxide should be avoided as it slows dissolution.

Hyperbaric oxygen can be considered for arterial gas embolism; however, clinical data is limited. Excessive fluid should be avoided to minimise oedema.

Abdominal Injuries

Primary abdominal blast injury is rare in survivors other than with blast in enclosed spaces and underwater. It most frequently presents late with signs of peritonism indicating visceral rupture, infarction and haemorrhage. Gas-containing organs of the abdomen, particularly the colon, are most commonly affected. Rarely, liver or spleen rupture may occur.

CT or focused assessment sonography for trauma (FAST) scanning will guide early management, but clinical suspicion in the days after the injury is even more useful given the likelihood of delayed presentation. Primary anastomosis for blast colorectal injuries is unwise because of the high incidence of leak (30%), so most patients require colonic diversion. [37]

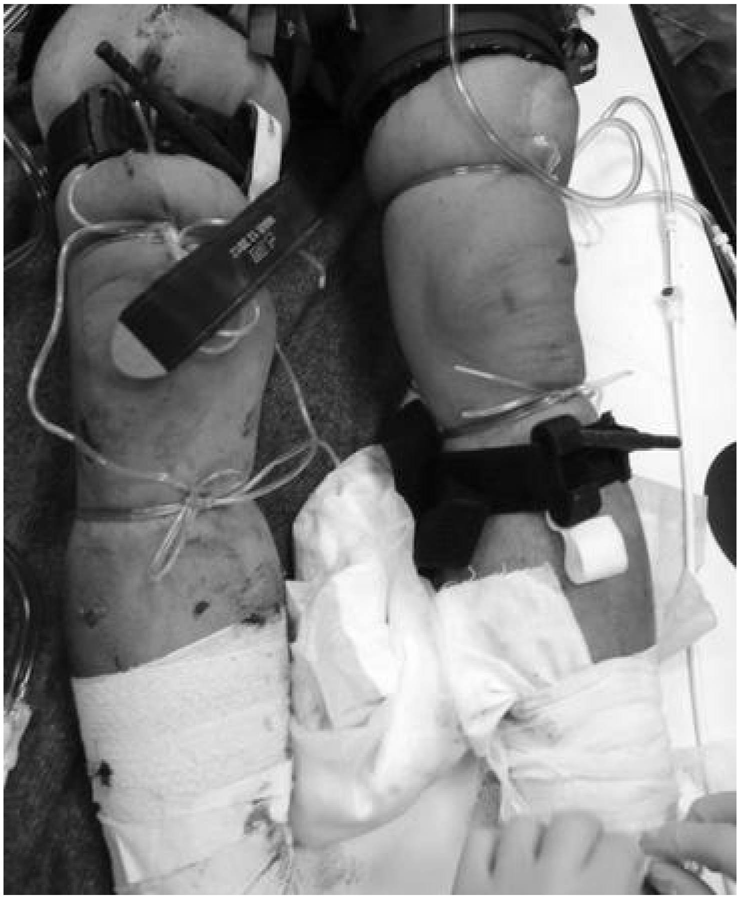
Brain Injuries

Traumatic brain injury (TBI) is a leading cause of mortality in blast victims, accounting for 50%–70% of fatalities. [38, 39] CNS blast effects include diffuse axonal injury, contusion, infarction from gas emboli and traumatic subdural haematoma. These are all managed according to conventional TBI guidelines. [40] A patient with brief loss of consciousness after blast should have brain CT or MRI if there is a persistent headache, vomiting, localising neurological signs or a Glasgow Coma Score less than 15, noting that TBI after blast can evolve over 48 hours, with around one-third missed on initial evaluation. [16] The role of primary blast injury in mild traumatic brain injury (mTBI) or chronic traumatic encephalopathy (CTE) is unclear. [41, 42]

Extremity Injuries

Extremity injuries, including fractures and traumatic limb amputations, are common in blast victims. The blast wave fractures long bones, and the wind then detaches the distal portion. This is thought to explain why such amputations are typically not through joints. [43]

Military experience has convincingly demonstrated the value of the prehospital windlass arterial tourniquet in stopping life-threatening bleeding in both blast and ballistic trauma (Fig. 107.5). Early fasciotomy to treat compartment syndrome should be considered.



The clinical photograph depicts both lower limbs of a patient lying on a flat surface. Each leg is wrapped with bandages at the lower portion and fitted with multiple tourniquets around the thighs and knees. Transparent tubing is looped around both legs and connected to medical devices, likely for fluid administration or monitoring. The skin exhibits discolouration, abrasions, and some areas of swelling. One leg has an intravenous cannula secured with tape.

FIG. 107.5 Prehospital improvised arterial tourniquets, insufficient to stop arterial haemorrhage, supplemented effectively by windlass Combat Application Tourniquets. Note the potential for iatrogenic tissue damage from the improvised devices. In hospital, standard

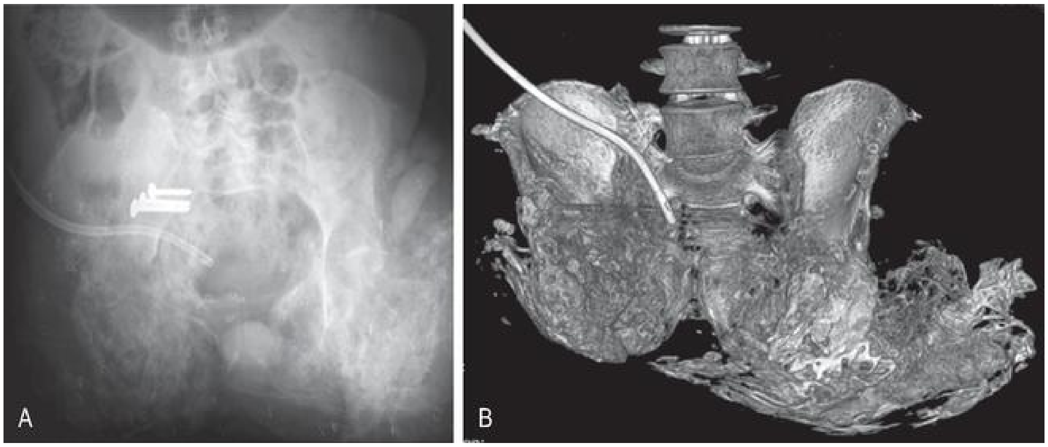
pneumatic tourniquets quickly replace prehospital devices. (Courtesy Australian Defence Force, Afghanistan, 2013.)

Quaternary and Quinary Injuries

The incidence of burns in blast victims varies depending on the source of the blast and proximity. Careful titration of fluid resuscitation is required due to the risk of exacerbating concomitant lung injury. Soft tissue wounds are prevalent and may be grossly contaminated with blast fragments, dirt, human remains or other debris. There is a high incidence of polymicrobial and invasive fungal infection in complex wounds. Early debridement and irrigation should be performed, and early broad-spectrum antibiotic and tetanus prophylaxis should be given. Other quaternary and quinary injuries, including chemical, biological and radiological weapon effects are beyond the scope of this chapter.

Heterotopic Ossification: A Late Complication of Blast Injury

Blast accentuates the risk of post-traumatic heterotopic ossification considerably, with an incidence as high as 64% (Fig. 107.6). [44] Heterotopic ossification is the formation of bone in muscle and soft tissues. It causes pain, ulceration and loss of function, along with poor fitting of prostheses. Very early prophylactic low-dose radiotherapy and non-steroidal anti-inflammatory drugs appear effective, but radiotherapy is impractical in the deployed environment and both are accompanied by risk of adverse effects. Surgical excision of extensive lesions remains the only effective treatment. [44]



The radiograph and three-dimensional scan show the pelvic region, labelled A and B. Part A is a frontal radiograph exhibiting the pelvis and lower lumbar spine with two metallic surgical screws inserted into the right iliac bone and a drainage catheter coursing laterally into the pelvic cavity. The surrounding soft tissue exhibits diffuse radiodensity. Part B is a three-dimensional reconstructed scan exhibiting the bony pelvis with detailed surface anatomy and metallic screws anchored into the pelvic bone.

FIG. 10.7.6 Radiograph (A) and three-dimensional CT rendering (B) of a patient with severe pelvic heterotopic ossification after bilateral hip disarticulations due to combat-related blast injuries. (From Alfieri KA, Forsberg JA Potter BK. Blast injures and heterotopic ossification. Bone Joint Res. 2012; 8: 192–197.)

Ballistic Trauma

Penetrating ballistic trauma can be caused by projectiles energised by explosive devices or by firearms.

Blast Fragmentation

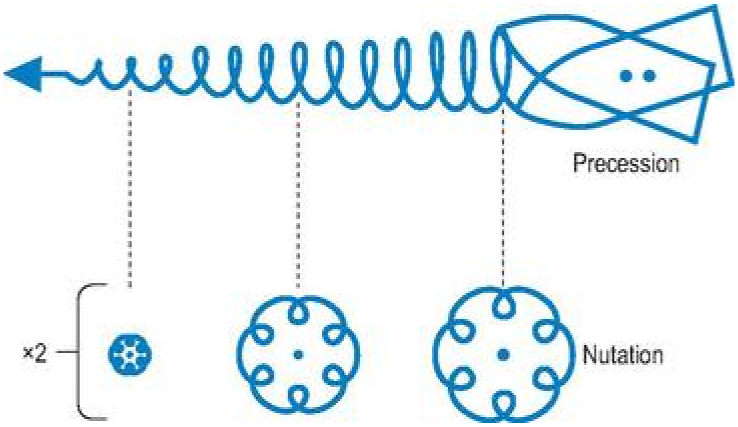
Casing fragmentation multiplies the range and effect of small blast weapons such as grenades, mines and mortar bombs. Larger blast weapons rely on their greater energy to create fragments from surrounding rocks or debris, or to cause structural collapse. Fragments from casings or surroundings are incorrectly referred to as ‘*shrapnel*’ (Henry Shrapnel (1761–1842)), which should be reserved for *preformed* projectiles within a canister munition scattered by an explosive charge. The term ‘improvised explosive device’ (IED) covers a wide range of weapons, from low-yield ‘homemade’ explosives that typified much of the post-2001 Afghanistan conflict, to powerful explosive-formed penetrators made from repurposed military munitions used to defeat armour during the post-2003 Iraq insurgency.

Bullets from Firearms

A *bullet* is a single projectile shot from a firearm. Modern bullets are attached to *cartridge cases* containing the *percussion cap* or *primer* and *propellant*; the entire structure forms a *round* of *ammunition*. Firearms firing bullets include *rifles* (with a long barrel that is ‘rifled’ with spiralling grooves inside that rotate the bullet, increasing gyroscopic stability), *revolvers* (handguns with chambers that rotate to present each round to the barrel) and other types of *pistol* (with short barrels but no rotating chambers). A *shotgun* with a smooth-bored barrel usually fires *shot* (many round metal balls) rather than a single-formed projectile.

Projectile Ballistics

Rapidly expanding propellant gas accelerates the projectile through the firearm barrel. Projectile trajectory is determined by gravity, air friction and pressure resistance, wind, contact with solid objects (causing *ricochets*) and stability in flight. Most bullets in flight have their centre of mass behind their centre of pressure, causing *yaw*; this is opposed by gyroscopic stability, leading to a composite movement of *spin* (rotation around the long axis), *precession* (rotation of the rotational axis) and *nutation* (swaying of the rotational axis as it precesses). During flight, yaw progressively reduces. A rifle bullet is therefore more likely to hit point-on after 100 metres of flight than after 3 metres (Fig. 107.7).[45,46]



The schematic diagram exhibits proton spin dynamics through a sequence of labelled structures. A leftward-pointing arrow is followed by a tightly coiled helical trajectory representing precessional motion. Three vertical dashed lines connect this spiral to circular cross sections below, exhibiting the progression of motion patterns. The leftmost section shows a pair of smaller circular spin paths, followed by increasingly complex swirling patterns moving to the right.

FIG. 107.7 Precession and nutation. Both decrease as the distance from the barrel increases. (From Volgas DA, Stannard JP, Alonso JE. Ballistics: a primer for the surgeon. Injury. 2005;36(3):373–379.)

Wound Ballistics

Wound ballistics describe the interaction between a projectile and the biological tissue it hits. The amount of energy that is transferred is determined by the:

- *kinetic energy (KE) of the projectile:* $\text{KE} = \text{mass} \times \text{velocity}^2/2 \times g$. The KE *transferred* to the tissue is $\text{mass} \times (\text{impact velocity} - \text{exit velocity})^2/2 \times g$;

- *rotational energy of the projectile in flight:* usually negligible;
- *shape and impact angle of the projectile:* an aerodynamically shaped bullet will impart more energy if it hits side-on; the degree to which this occurs is determined by its properties in flight, including the distance travelled and whether it has hit anything during flight;
- *projectile deformability and fragmentation;*
- *degree to which the projectile 'tumbles':* many, but not all, bullets tumble through 180° after hitting biological tissue and come to lie base-first. Tumbling, along with cavitation (below) is the reason why full metal jacket exit wounds are often larger than entry wounds; and
- *specific gravity of the tissue hit* . [47]

The terms 'high' and 'low' velocity (typically demarcated at 2000 ft/sec) are not as useful as 'energy', incorporating projectile mass, and even less useful than the concept of energy transfer. Although most rifles are 'high-energy' and most pistols 'low-energy', this is only one determinant of wound magnitude. A 'high-energy' rifle bullet may cause less trauma if it misses ribs and traverses a short path through the chest than a 'low-energy' pistol bullet that fragments after hitting a rib. Notwithstanding this, the KE of most rifle bullets is many times that of a pistol (e.g. a NATO 5.56 mm rifle bullet has a muzzle energy of 1859 joules, compared to 538 joules of a military 9 mm pistol bullet). Hitting bone, a pistol bullet frequently causes a simple fracture, whereas a rifle bullet causes extensive bone fragmentation. [48] Most individual wounds caused by blast fragmentation are low-energy transfer, but the total energy transfer caused by multiple projectiles can be substantial.

Further determinants of projectile effect are:

- the function of the tissue (e.g. the eye is damaged by minimal energy transfer)
- the ability of the affected tissue to tamponade haemorrhage (e.g. liver bleeds more than muscle).

Bullet Deformability

Bullets are typically made of lead or lead–antimony, as high density preserves KE in flight. Lead bullets melt at greater than 2000 ft/s (≈600 m/s), [47] necessitating a ‘full metal jacket’ (a misnomer, as the base of the bullet may have no covering) of harder metal (e.g. copper/zinc, copper/nickel or steel). Military bullets (according to the Third Hague Convention of 1899) must not flatten on contact with the body, thereby reducing energy transfer and wound size, so avoiding ‘unnecessary suffering’. The ‘full metal jacket’ therefore serves two purposes: increased accuracy and reduced lethality. By increasing the chance of non-lethal injury, an unintended consequence is to increase combat effect: a wounded enemy soldier consumes more resources than one who is dead. In contrast, hunting rifle bullets have a soft lead or polymer tip, increasing the chance of killing quickly and so reducing suffering. Pistol bullets with deformable points are less likely to exit the target, beneficial for police wishing to reduce risk to bystanders. Substantially lower energy compared to rifle bullets means deformable pistol rounds do not appreciably increase mortality.

Doctors are sometimes asked by people concerned with compliance with the Laws of Armed Conflict to classify the type of bullet found in a patient. *Any* bullet can deform and fragment. For example the NATO 5.56 mm bullet typically fragments into two at reproducible wound depths. Finding no intact fully jacketed bullets does not allow this question to be answered. [49]

Mechanisms of Tissue Damage

Bullets cause crushing/laceration, shock waves and cavitation. Crushing and laceration are caused by the direct force of the bullet, and are the principal mechanisms of injury due to ‘low-energy’ firearms. The inertia imparted to tissues by a high-energy bullet causes cavitation: as the tissues continue to move away from the bullet track, sub-atmospheric pressure sucks in debris. The *temporary cavitation* disrupts cells and their microcirculation, producing dead tissue around the wound track *up to* 30–40 × the bullet diameter. [47] Surrounding this necrotic tissue are the *zone of* *extravasation* , containing some fractured capillaries and inflammatory infiltrate, and the *zone of concussion* , containing vasodilated vessels and atypical myocytes. Much of the zone of extravasation is potentially viable with adequate resuscitation; the zone of concussion should recover. Cavitation depends on tissue elasticity; for example liver is more affected than the muscle. The temporary cavity collapses to a much smaller permanent cavity, but the size of the permanent cavity is not an indicator of the extent of devitalised tissue. Inelastic gelatin blocks overemphasise the implications of temporary cavitation in many tissues,[50,51] and are additionally misleading by not replicating the effect of passage through tissues of different densities along the bullet track.

Management of Penetrating Ballistic Trauma: Basic Principles

The International Committee of the Red Cross (ICRC) recently updated its guidelines to recommend ‘adequate’ rather than ‘thorough’ wound excision, limited to ‘removal of necrotic tissue, contaminated debris, organic foreign material, and blood clots’, recognising the difficulty of defining extent of necrosis at initial surgery and (if resources allow) better outcomes that result from more limited but repeated debridement. Longstanding principles of leaving wounds open; fascial decompression; avoiding unnecessary dressing changes; limb immobilisation pending soft tissue healing; delayed primary closure; antibiotics, antitetanus and analgesia; and early physiotherapy, all remain.[5] Prohibition of internal fixation has been modified to at least permit consideration ‘only in skilled hands and with excellent conditions of hygiene and nursing care’.

Damage Control Surgery then Definitive Management

Damage control surgery aims to stop haemorrhage, restore blood flow and control wound contamination.[52] Wounds are packed and temporarily closed if necessary. Restoration of bowel continuity, definitive debridement and wound closure are all deferred until physiology is optimised.

In general, re-inspection within 24–48 hours will be required for major wounds, with further debridement if required. This process continues every

48 hours until wound closure. Even apparently clean wounds should not be closed before 4–5 days. Of 16,172 patients in the ICRC database, 41% required two operations, 14% three and 20% four or more.[5] Serial debridement is resource-intensive; in mass casualties or resource-poor environments, the ICRC recognises this approach may be impossible and still advises wider initial excisions.[5]

Management of Specific Types of Penetrating Ballistic Wound

Extremity Wounds: Wounds that Do Not Require Debridement

Military[53] and civilian[5] guidelines agree that not all bullet wounds require debridement. Extremities with entry and exit wounds <1 cm and no swelling or signs of injury to vital structures can have narrow skin margins excised and the channel irrigated with gravity-fed crystalloid. Wounds that do not penetrate deep fascia require only scrubbing, irrigation and antibiotics.

Extremity Wounds: How Much Tissue to Debride?

Many published accounts[7,50,54] and the authors' own experience suggest that surgeons sometimes perform extensive debridement around high-energy bullet tracks, believing microvascular tissue damage is more extensive than can be seen. This approach, once advocated in military texts,[55] ignores empirical studies[54] and the distinction between projectile energy and energy transfer.

In penetrating ballistic trauma, muscle viability was historically assessed using the 'four C's'[10] – *capillary* bleeding when cut, *contraction* when pinched, *colour* of red meat and firm *consistency* . However, apparently dead muscle is often later found to be viable.[50,51,56] Along with substantial consensus,[10,42,57,58] we advocate initial debridement of only tissue and bone that is clearly ischaemic or not attached, with reassessment after 2–3 days.

Superficial Blast Fragmentation

There is debate about the optimal management of blast fragmentation penetrating trauma. Historically, military teaching was that all wounds should be surgically debrided, as most fragments carry bacteria. However, few open wounds develop infection, [59] implying at least some can be managed non-operatively. The smaller superficial wounds in Fig. 107.3 were cleaned with a surgical scrub brush; no infection developed and the resultant scars were smaller than if each perforation had been explored. Published indications for surgical debridement of blast-fragmentation wounds derived from case series are listed in Table 107.6 . [60] , [61]

Table 107.6

Indications for surgical debridement of blast-fragmentation wounds

Ordog et al. (1993) [60]	**Bowyer (1997)** [61]
Presentation >24 hours after wounding, without basic cleansing before presentation	Involvement of bone, pleura, peritoneum or major vessels
Wound size >1–2 cm	Wound entry or exit >1–2 cm
Failure to comply with wound care instructions	Evidence of wound cavitation
Factures	Obvious signs of infection
	Wounds due to buried mines

Ballistic Fracture Management

Bone fragments without any soft tissue attachments should be removed. [48] However, *any* soft tissue attachment makes assessment of viability difficult, and at initial surgery, such fragments should be retained. High-energy transfer fractures and fractures of the proximal tibia and fibula [62] often require fasciotomy to prevent compartment syndrome. Infection risk argues strongly for plaster, external fixation or traction rather than internal fixation. [63, 64]

Abdominal Penetrating Wounds

Low-energy bullets and blast fragmentation tend to produce discrete injury to abdominal organs. Up to 30% of civilian anterior abdominal and 67% of lower back gunshot wounds can be managed safely without surgery. This approach is increasing in US civilian practice, [65] associated with better and more widespread CT imaging; however, it fails in 21% of cases, and failure is associated with increased mortality. [65] High-energy transfer, haemodynamic instability, peritonitis or lack of reassuring imaging all indicate laparotomy. In the military context, definitive surgery can avert a more prolonged admission for observation. Without comprehensive imaging, it is our practice and that of others [59] to explore all penetrating abdominal wounds. If CT imaging is available, in the light of observational studies, [66] UK military guidelines allow for a selective non-operative approach in the minority of casualties with no peritonitis or haemodynamic instability who can be intensively monitored. [67]

Thorax

Penetrating thoracic injury is either rapidly fatal (e.g. 93% of patients with aortic injuries die before reaching hospital [68]), or managed with simple measures. Eighty-five percent of penetrating thoracic trauma patients who reach medical care can be successfully managed with intercostal catheter (ICC) drainage alone. [69] To prevent further haemorrhage, an ICC should be placed through a new incision rather than the wound. On placement of the ICC, Early Management of Severe Trauma [70] teaching is that >1500 mL initial haemorrhage or >200 mL/h ongoing loss for >2–4 hours necessitates thoracotomy. Emergency anterolateral thoracotomy should be considered in patients with penetrating thoracic injuries who arrive pulseless but with ECG activity within the preceding 6–10 minutes, with the intention of releasing cardiac tamponade, controlling haemorrhage by direct repair or cross-clamping the aorta or pulmonary hilum and allowing internal cardiac massage to ‘buy time’ for aggressive fluid resuscitation. There is little benefit to closed chest compressions in hypovolaemic traumatic cardiac arrest and efforts should be focused on aggressive fluid resuscitation and haemorrhage control.[71] Thoracic penetrating injury below the level of the nipple, a positive FAST scan or abdominal signs suggests the projectile has traversed the diaphragm.

Retained Foreign Bodies

Easily accessible projectiles should be surgically removed. However, projectiles buried in healthy tissue (including the brain) *unequivocally do not need to be removed*, with some exceptions:

- those lodged in joints or the subarachnoid space, in order to prevent lead arthropathy and systemic toxicity, joint destruction or neural damage;
- those that appear to become the source of systemic infection;
- those lying next to an internal organ (e.g. bronchus and heart), with the risk of subsequent erosion[51]; and
- those causing persistent pain, with the caveat that the psychological effects of a retained projectile are often profound, and this can influence pain perception.

Blood lead levels from projectiles retained in muscle peak at 1 month and in synovial fluid at 6 months.[72] If lead toxicity is the sole indication for projectile removal, the threshold serum levels are 10 µg/dL in children and 40 µg/dL in adults. Projectile removal should be attempted only after chelation with EDTA, dimercaprol, d-penicillamine or succimer.[5]

Helpful Investigations

Pre- and intraoperative physical examination is the best single method of evaluating ballistic wounds.[54] However, projectiles often follow unpredictable paths. Radiology can be useful in triage, operative planning and selection of cases for non-operative management. The extent of blast-fragmentation wounds such as those in Fig. 107.8 would be almost impossible to assess without radiology. In Iraq and Afghanistan, all patients with substantial ballistic trauma had whole-body CT if this was available unless immediate life-saving surgery was required. Wound paths can be plotted using CT images, allowing surgical planning (Fig. 107.9).

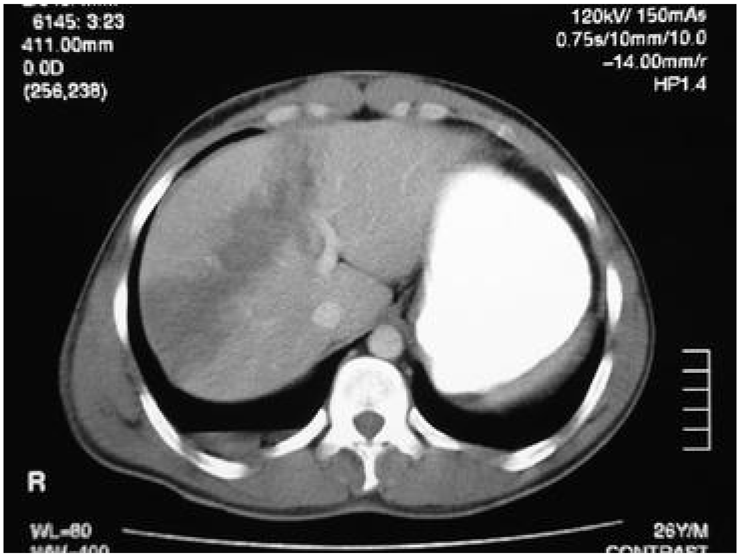
The radiographic view exhibits a frontal view of the lower torso extending from the lower abdomen to the upper legs. Numerous small, round metallic fragments are dispersed throughout the pelvic and upper thigh regions, concentrated on the left side. Medical tubing and a catheter are also visible, running diagonally from the right pelvic area to the lower left leg.

FIG. 107.8 Scout CT image showing numerous metallic fragments after blast-fragmentation injury from an improvised explosive device. (Courtesy Australian Defence Force, Afghanistan, 2012.)



The cross-sectional C T scan of the upper abdomen depicts anatomical structures, including the liver on the left side of the view, the spleen on the right, the spine centrally positioned at the bottom, and adjacent soft tissues. Radiographic labels and technical parameters, including thickness and imaging settings, are displayed.

FIG. 107.9 CT image demonstrating the wound track of a 9 mm bullet through the liver. (Courtesy Dr Daron Cunningham, Cape Town, 2003.)

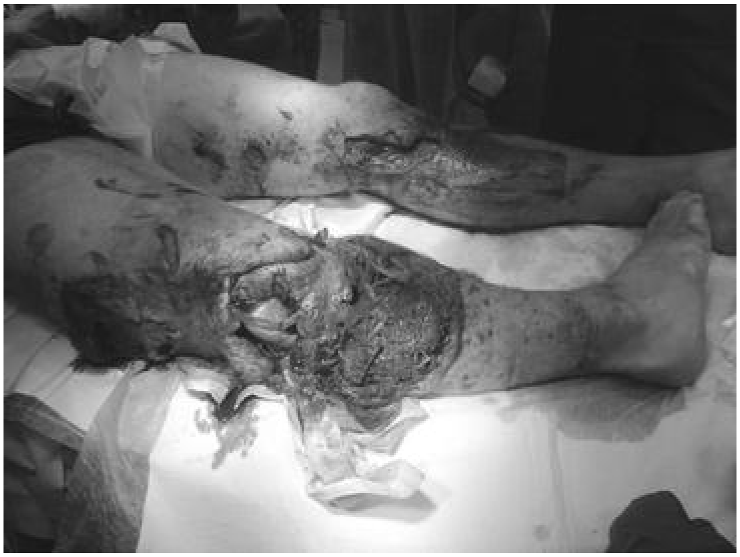
ICRC Wound Classification

The ICRC wound classification system [5] categorises disease severity by measuring the size of the entry wound, exit wound and wound cavity and involvement of fractures, vital structures and metallic foreign bodies. The result is a grade and type of wound. Unable to capture all aspects of anatomy and physiology and not accounting for multiple wounds, the ICRC system is a poor predictor of outcome, but is nevertheless useful for quantifying the effects of weapon systems.

Special Cases of Ballistic Trauma

Landmines and Improvised Explosive Devices

Antipersonnel landmines wound by a combination of blast and fragmentation from their casing and from rocks and soil. Buried mines explode upwards through the leg, commonly resulting in traumatic amputation through the midfoot or distal tibia, with debris driven up fascial planes (Fig. 107.10). Wound severity depends on the quantity of explosive, point of foot contact, debris near the mine and footwear. [55] Bounding mines contain two charges: a small explosion propels a tethered casing upwards to 1–2 metres, which then explodes propelling fragments 50–100 metres. Horizontal spray mines also cause most of their effect by blast fragmentation. Air-dropped ‘butterfly’ mines rely on primary blast effect to maim when handled. Improvised explosive devices often mimic the effects of mines, but being made from anything from artillery shells to household chemicals, their effects are more difficult to predict. The principles articulated above apply to mine wounds, with particular emphasis on removing soil. Topical negative-pressure dressings accelerate wound healing and reduce hospital length of stay compared to traditional frequent dressing changes. [73]



The clinical photograph shows a patient lying in a supine position on a treatment table, with both legs exposed. The right leg shows extensive soft tissue trauma, with large open wounds revealing underlying muscle and tissue loss around the thigh and knee area. The left leg has visible bruising, swelling, and surface damage along the shin.

FIG. 107.10 Extensive wound contamination and tissue loss due to blast fragmentation from an improvised explosive device. (Courtesy Australian Defence Force, Afghanistan, 2013.)

Incendiary Devices (Napalm, White Phosphorous)

Military forces use white phosphorus and napalm as incendiaries, and white phosphorus is also used to create smokescreens. However, both are effective psychological weapons due to their capacity to inflict severe wounds. Napalm produces an adherent gel producing full-thickness burns involving muscle. A 10% burn typically causes rhabdomyolysis and renal failure. [5] Napalm commonly undergoes incomplete combustion, so carbon monoxide poisoning is common. White phosphorus fragments on explosion and ignites on air contact. Immediate treatment is to scrape off visible particles followed by keeping the wound moist to exclude air. Dilute (1%) copper sulphate makes white phosphorus safer and easier to remove by turning it black. Alternatively, phosphorus particles glow in low light. Systemically absorbed white phosphorus causes hypocalcaemia and hyperphosphataemia, requiring intravenous calcium.[74]

Behind Armour Blunt Trauma (BABT)

Body armour, consisting of woven textiles and ceramic plates, effectively reduces the lethality of ballistic trauma. However, rifle bullets larger than 5.56 mm can still kill by transmission of a force wave.[75] The immediate effects of BABT are vagally mediated apnoea and hypotension,[76] commonly accompanied by pulmonary and myocardial contusion, rib fractures, haemo- and pneumothorax.

Infection in Ballistic Injury

The two requirements for serious wound infection – dead tissue and a deep inoculum of bacteria or fungi – are frequently present in ballistic trauma. This is particularly true of military wounds, with typically 3–6 different bacterial species isolated compared with only one in infected civilian wounds.[48] Microorganisms are mainly introduced into gunshot wounds by cavitation, but the bullet is not sterilised by firing and can also lead to infection.[47] Historically, major causative organisms have been beta-haemolytic streptococci and clostridia. Although ‘the best antibiotic is good surgery’,[5] infection with both organisms is effectively prevented by prophylactic penicillin. Antibiotics alone may be sufficient for wounds left open with sufficient drainage.[77] US 2011 consensus guidelines for antimicrobial prophylaxis of combat-related wounds, drawing on experience of modern conflict, remain sound and were re-endorsed by the US Joint Trauma System Clinical Practice Guidelines in 2021.[78] Essential points are summarised in Box 107.1 . Prehospital administration of prophylactic antibiotics, especially in the military context of prolonged evacuation times, reduces wound infection. [79]

Box 107.1

Infectious Diseases Society of America and Surgical Infection Society guidelines for the prevention of infections associated with combat-related injuries [78]

IV antibiotic prophylaxis is indicated as soon as possible (ideally <3 hours) after wounding.

Cefazolin 2 g IV every 6–8 hours (+metronidazole 500 mg IV q8–12 hours for oesophageal, abdominal organ, CNS) is appropriate for all wounds except penetrating eye injury, for which levofloxacin 500 mg IV/PO once daily is recommended.

Alternate agents depend on site of wounding:

- Extremity; thoracic (excl. oesophageal); maxillofacial: Clindamycin (300–450 mg PO TID or 600 mg IV q8 h)
- Oesophageal; abdominal: Ertapenem 1 g IV or moxifloxacin 400 mg IV
- CNS: Ceftriaxone 2 g IV q24 h. Consider adding metronidazole 500 mg IV q8–12 h if gross contamination with organic debris. For penicillin-allergic patients, vancomycin 1 g IV q12 h plus ciprofloxacin 400 mg IV q8–12 h

Duration of therapy in the absence of signs of infection: extremity; thoracic – 1–3 days; abdominal – 1 day after definitive washout; maxillofacial – 1 day; CNS: 5 days or until CSF leak is closed, whichever is longer

Tetanus toxoid and immune globulin should be used as appropriate to immunisation status.

Enhanced gram-negative coverage with aminoglycoside or fluoroquinolone is not recommended.

Addition of penicillin to prevent clostridial gangrene or streptococcal infection is not recommended.

Redose antimicrobials in the setting of large volumes of blood produce resuscitation.

Use only topical antimicrobials for burns.

Soil potentiates the ability of contamination to cause infection. Wounds contaminated with soil should be thoroughly cleaned, potentially requiring more wound excision than otherwise. Infection is also particularly likely in haematomas, [51] which should be drained. If a wound requires debridement, earlier surgery is associated with less infection. For example the 10% infection rate in wounds debrided in less than 6 hours after wounding rose to 25% in wounds debrided later. [80]

Conclusion

Medical planning and training in the management of ballistic trauma require balancing modern evidence-based medicine with the study of lessons acquired over centuries of conflict. Combatants might repeat mistakes of the past; doctors should not.

Chemical, biological, radiological and nuclear exposure management

Andrew McDonald Johnston and Sophia L. De Maria

Introduction

Chemical, biological, radiological and nuclear (CBRN) weapons have all been used as weapons of war, terrorism or assassination in the period from the First World War to the present. Their use by states against adversaries continues up until the present day with well-described incidents in the United Kingdom and the Middle East. Many states had historical chemical and biological weapons programmes, and many continue to have nuclear weapons or aspire to obtain them. [1]

The use of these weapons is prohibited under the Chemical Weapons Convention [2] which most countries have signed up to. All of the officially declared international stockpiles of chemical weapons have been destroyed, however, it is possible that some nations have undeclared stocks. Similar conventions exist for biological weapons and there is a non-proliferation agreement for nuclear weapons. In spite of this, various terrorist organisations have expressed a desire to obtain or use CBRN weapons.

The Chemical Weapons Conventions aim to prevent CBRN agents from being manufactured, destroy the stock of existing chemical weapons, destroy or convert any production facilities and restrict the sale of various precursors of chemical weapons. States that are signatories to the conventions must allow independent inspection of their facilities.

Recent targeted assassinations in the United Kingdom, Russia and South East Asia, the use of sarin in Tokyo and the use of chemical agents including chlorine and sarin in Syria have shown that there is an enduring threat from CBRN weapons.

As many of these agents can cause large numbers of casualties with respiratory failure, intensive care professionals need to know how to recognise their use and prepare to deal with them. This particularly applies to nerve agents such as sarin, and lung-damaging agents such as phosgene and chlorine.

The typical route of exposure in large-scale chemical weapons attacks is inhalational, although transcutaneous absorption is also possible for many of the nerve agents, including the organophosphorus nerve agents such as Sarin and the Novichok nerve agents. Blister agents (e.g. sulphur mustard), directly affect the skin as well as cause respiratory effects. Ocular involvement may be a feature even at low concentrations both of nerve agents and irritants such as riot control agents and toxic industrial chemicals, including chlorine and sulphur mustard. Ingestion is a less likely route of exposure in large-scale attacks but may be the route of exposure in targeted assassinations.

CBRN attacks may also target infrastructure, aiming to deny the use of facilities or geographical areas using persistent agents, and may take aim at agriculture, including targeting livestock animals with bacterial agents such as anthrax, or crops of economic value with chemical or viral agents.

Diagnosis

Diagnosis of exposure to CBRN weapons is context specific. In many cases of individual exposure, the fact that the affected individual was politically active or a critic of a regime known to have worked on CBRN weapons was the key to making a diagnosis when they presented with unusual symptoms and signs. In mass casualty incidents involving unusual symptoms and signs, CBRN weapon use should be considered. [3] This also applies to terrorist explosions where the use of CBRN agents in addition to conventional explosives needs to be considered.

Emergency response agencies at the scene of a terrorist incident may have the ability to identify any CBRN agents released, however, the results may not be available before patients arrive at the hospital. For specific agents, it may be possible to detect the agent involved from clinical samples using regional or national poison centres with access to advanced analytical facilities. Attribution of responsibility is more difficult but may be possible with the help of national laboratories or the Organisation for the Prohibition of Chemical Weapons.

CHEMICAL AGENTS

Chemical agents include weapons of war such as sulphur mustard, nerve agents, hydrogen cyanide, phosgene and other highly toxic chemicals, but also toxic industrial chemicals which may be released deliberately or accidentally during terrorist incidents or warfare. [4]

Riot Control Agents

Riot control agents are prohibited for use in conflict by the Chemical Weapons Convention but are allowed in certain civil disorder situations. Riot control agents include a range of chemicals often referred to as tear gases, the most common being CS, 2-chlorobenzylidene malononitrile and pepper spray/gas, oleoresin capsicum. [5] These riot control agents are not nerve agents. The agents work on transient receptor potential channels, mostly involved in nociception.

Riot control agents are typically dispersed in a powder form or as a liquid in a carrier solvent as a spray, and may also be generated by burning a filler in a grenade form.

Riot control agents cause severe skin and mucosal irritation, including severe lacrimation, inability to keep eyes open, severe nasal irritation and cough. Some people who are exposed will be completely incapacitated. Safety studies were mostly conducted in the 1950s on men, and there are indications that in crowd control situations, women are likely to be more seriously affected.

Treatment is supportive. In most exposed people, symptoms will resolve in 10–30 minutes. Usual clinical PPE should be sufficient for healthcare workers and as with many agents, lifesaving interventions such as control of catastrophic haemorrhage and airway management take priority. Tear gas will blow off the body or can be washed off with copious amounts of water. Powder residue can be wiped off the face with a moist wipe.

Riot control agents can be fatal, either due to the pyrotechnic component of tear gas grenades causing fires in confined spaces or by high concentrations causing respiratory distress, particularly in patients with pre-existing respiratory illness. The projectiles used in some situations to deliver the agents can cause direct injury, including blunt trauma, eye injuries and penetration of brain or body cavities, with numerous deaths reported.

Sulphur Mustard (Mustard Gas)

Sulphur mustard is an oily liquid blister agent (or vesicant) that causes burns to skin, mucosa and eyes. Although it is often referred to as mustard gas, it is liquid at environmental temperatures. The severity of the burn is proportional to the concentration of mustard, with damage occurring within minutes of exposure, but with a delayed onset of symptoms. Systemic effects can occur after some delay with a leucopoenia occurring after a few days to a week and effects on multiple other organs. [6] Mustard burns can range from mild superficial erythema and itch to large confluent blisters and desquamation. Involvement of eyes and moist intertriginous areas is common and can be incapacitating. Sulphur mustard is heavier than air, and collects in low-lying areas such as trenches and building basements. High concentrations may cause severe airway burns and respiratory failure.

Management of sulphur mustard exposure involves rapid decontamination and then supportive care. Patients with extensive skin involvement should be resuscitated for thermal burns, though with supportive care, they may not need skin grafting. There is little contemporary literature on skin grafting in mustard agent exposure. Corneal involvement also resolves with careful eye care and in many patients, visual loss will be only temporary.

Nerve Agents

The organophosphorus nerve agents are chemicals that interfere with neuromuscular transmission and also have autonomic and central nervous system effects. Agents in this class include sarin, tabun, soman and VX, although there are also numerous others, including Novichok agents. They vary both in potency and in physical properties such as volatility, water and lipid solubility that affect their persistence in the environment and rate of absorption.

Nerve agents inactivate acetylcholinesterase enzymes, leading to the accumulation of acetylcholine in synapses and a range of harmful effects. They also have central nervous system effects not directly mediated by acetylcholinesterase inhibition but instead due to excitotoxicity in status epilepticus. [7]

The toxidrome of nerve agent poisoning includes miosis, bradycardia, increased secretions, muscle weakness and fasciculations, involuntary defecation and urination, respiratory distress progressing to respiratory arrest, confusion, reduced conscious level and seizures. Death is through respiratory muscle paralysis.

The characteristic toxidrome of nerve agents should make a clinical diagnosis possible, although the route of exposure may change the temporal manifestation of symptoms and signs. Inhalation of nerve agents may present a different initial clinical picture from transcutaneous exposure, where the whole constellation of symptoms and signs may not be immediately present but may evolve over time.

Insecticide poisoning by ingestion of carbamate or organophosphorus insecticides is a common global problem and has a similar toxidrome to nerve agent exposure.

Oximes, atropine and benzodiazepines are used to treat nerve agent poisoning. There are several oximes that may be used, with different activity against the various nerve agents. Newer oximes may have broader activity against a wider range of nerve agents, however, pralidoxime and obidoxime are those that are commonly available (Table 108.1) . [8]

Table 108.1

Nerve agent toxidrome and treatment

Nerve agent toxidrome
Acetylcholinesterase inhibition causing a severe cholinergic syndrome
Muscarinic effects
Chest tightness
Dyspnoea
Copious respiratory secretions
Foaming at mouth
Bronchospasm
Bradycardia
Hypotension
Abdominal pain
Vomiting
Diarrhoea
Sweating
Miosis
Nicotinic effects
Fasciculation – may be continuous and prolonged
Paralysis
Central Effects
Anxiety
Hallucinations

Confusion

Seizures

Respiratory failure

Death

Treatment

Decontamination – very important due to the risk of ongoing transcutaneous absorption

Atropine – high dose, repeated and prolonged treatment may be required

Oximes – reactivate cholinesterase if given early

Benzodiazepines – reduce central nervous system effects, control seizures

Supportive care, airway interventions and intubation and mechanical ventilation may be required

In insecticide poisoning, meta-analyses suggest that oxime therapy is ineffective.[9,10] However, in the setting of civilian poisonings in rural areas, there is often a significant delay in patients presenting to hospital as well as confounding effects from the toxic organic solvents used in insecticides.[11] Animal studies and military experience in historical conflicts strongly suggest that early oxime administration is effective in reducing the severity of nerve agent poisoning.

Early administration of oxime therapy is essential as there is an irreversible ‘ageing’ effect with time-dependent binding of nerve agents to acetylcholinesterase. Once this has occurred effects of the nerve agent will continue until the patient synthesises enough cholinesterase to restore synaptic function, which can take days to weeks depending on the specific agent involved. Alongside oxime treatment, high doses of atropine should be administered, with typical initial doses being 2 mg repeated every 5–10 minutes until the heart rate rises above 90 beats per minute and secretions and sweating are reduced. Very high doses of atropine may be needed and prolonged treatment may be required, particularly for longer-acting nerve agents. Pupil miosis may not respond to atropine after exposure to volatile nerve agents such as sarin. Central nervous system effects of nerve agents, including agitation and seizures, should be treated with benzodiazepines. Patients with respiratory failure may require intubation and mechanical ventilation. There is also a risk of ‘intermediate syndrome’ with recovery from poisoning, followed by respiratory failure 2–4 days later requiring respiratory support. [12]

Novichok or newer generation nerve agents have been used in a small number of targeted political assassinations, [13] with one well-characterised politically motivated poisoning described. [14] The patient had a characteristic cholinergic syndrome but with dilated pupils (possibly due to treatment). Bradycardia, myoclonus, hypersalivation and hypothermia were present. The diagnosis was confirmed by the finding of severely impaired plasma butyrylcholinesterase levels. The patient responded to atropine and obidoxime, although without any reactivation of cholinesterase activity. The patient then required continuous atropine treatment for 10 days, in spite of which they had ongoing myoclonus that was resistant to therapy. This patient required more than three weeks of mechanical ventilation. Their cholinesterase activity only improved very slowly, though a transfusion of fresh frozen plasma was effective in increasing the levels. Specialised laboratory testing identified a Novichok agent in the patient’s blood. [14]

Novichok agents are notable for their prolonged duration of action, with severely affected patients requiring prolonged mechanical ventilation and critical care.

Phosgene

Phosgene ($COCl_2$) is a lung-damaging agent that was used in the First World War. It is used in many industrial chemical processes and sporadic cases of phosgene poisoning occur in industrial accidents. Phosgene causes the delayed onset of dose-dependent symptoms. At low doses, minor eye and respiratory irritation occur. At higher doses, phosgene exposure manifests as frank lung injury. Cough, chest pain, burning sensations and dyspnoea are common. Clinical signs may include crepitations on auscultation. Phosgene causes a complex inflammatory response with increases in lung permeability resulting in severe pulmonary oedema. There are no specific antidotes so treatment is supportive. Animal studies suggest that steroid treatment does not improve lung injury after phosgene exposure. [15]

Chlorine

Chlorine gas is used extensively in industrial applications. It has been used in terrorist and state attacks on civilian populations, delivered in barrel bombs by air or by exploding large industrial chlorine cylinders. Because it is heavier than air, people sheltering in low-lying areas such as cellars may be particularly affected. It is non-persistent and disperses rapidly if used in open spaces. Chlorine is a respiratory irritant which causes mucosal irritation, with eye and nasal pain, chest pain, cough and in high doses, respiratory failure. [16] Imaging may show lung infiltrates. Treatment is predominantly supportive, as for other causes of respiratory failure.

Hydrogen Cyanide

Hydrogen cyanide is dispersed as a gas and causes the rapid onset of dyspnoea, seizures, collapse and coma followed by death from anoxia caused by the inactivation of the respiratory chain enzyme cytochrome oxidase. Symptoms may be non-specific at lower exposures. Hydrogen cyanide gas does not persist for long in the environment.

Elevated lactate may be found in higher exposures, and confirmation is by laboratory measurement of cyanide in blood or urine. Due to the rapid onset of hydrogen cyanide toxicity, treatment should be based on clinical findings and not laboratory results. [17]

Treatment is with high inspired oxygen concentrations, supportive management and amyl nitrite. In severely poisoned patients, specific antidotes should be used. These include sodium nitrite and sodium thiosulphate, dicobalt edetate or high-dose hydroxocobalamin. Dicobalt edetate is itself toxic, particularly if the clinical diagnosis of cyanide poisoning is incorrect. Newer experimental treatments may soon be available. [18]

Toxic Industrial Chemicals

A wide range of chemicals used in various industries are toxic. They may be used deliberately by terrorist organisations or may be released inadvertently by attacks on industrial facilities. There are too many of these to cover, but the most relevant ones include chlorine and phosgene. For the majority of these chemicals, treatment is supportive. [17]

Pharmaceutical-Based Agents

These include opioids or fentanyl derivatives that are designed as incapacitants but have a narrow therapeutic index, so may cause rapid death from respiratory suppression. Little is published about these agents. [19] Management is with high doses of naloxone, for opioid overdose. Prolonged treatment with intravenous infusions of naloxone may be required.

There are theoretical reasons to believe that cell receptors other than opioid receptors might be targeted by future pharmaceutical-based agents.

BIOLOGICAL AGENTS

Biological agents are specific bacteria, viruses and fungi that are of concern because of their lethality, transmissibility or because they have historically been researched as agents by states with biological warfare programmes. [20] It is important to remember that for bacterial agents in particular, if a hostile state plans to use these offensively, the expectation is that the bacteria will have been engineered to be antibiotic-resistant, significantly complicating treatment.

Anthrax

Anthrax is caused by the gram-positive, rod-shaped bacteria, *Bacillus anthracis* . Anthrax was a component of many historical biological weapons programmes because of its potential to cause mass casualties as well as the susceptibility of grazing animals to its effects which made it a potentially highly effective weapon against agricultural economy. Anthrax is disseminated as spores, with a small number of spores potentially causing large numbers of infections. In natural outbreaks, sporadic cases of inhalational anthrax occur as well as gastrointestinal infection in animals that have scavenged the corpses of other animals that have died from anthrax.

Bacillus anthracis infection may be caused by inhalation, ingestion or inoculation of spores. Inhalational anthrax is the likely consequence of the deliberate release of anthrax spores. Spores are inhaled and then taken up by cells in the lung where they subsequently germinate over a period of days to months.

The anthrax bacterium has two plasmid-encoded virulence factors, responsible for its capsule and its toxins. Firstly, the bacterium is protected against neutrophil phagocytosis by its poly-γ-D-glutamic acid capsule. Secondly, the bacterium produces two binary toxins that are responsible for its lethality. These are the enzymatic proteins lethal factor and oedema factor which each combine with a cell entry protein, protective antigen, to gain entry to cells and form toxins which interfere with the immune response to infection. Lethal factor combines with protective antigen to form lethal toxin which kills macrophages and inhibits cell proliferation. Oedema factor combines with protective antigen to form oedema toxin which increases host intracellular cAMP, causing oedema and interfering with cell signalling.

Several anthrax vaccines and monoclonal antibodies are available which target the protective antigen, preventing the formation of the toxins. Anthrax immune globulin may also be available in some countries.

Clinical presentation is of atypical pneumonia with high fever and rapid progression to sepsis and death if untreated. Imaging may show mediastinal lymphadenopathy as well as lung infiltrates. [21] Computed tomographic imaging may show haemorrhage into mediastinal lymph nodes.

Treatment consists of broad-spectrum antibiotics with activity against anthrax, e.g. a quinolone with an additional penicillin. It should be noted that spores may continue to germinate in the lung for months after exposure. As a result, post-exposure vaccination should also be carried out to reduce the chance of infection after the antibiotics have been stopped. A worrying aspect of anthrax in deliberate release situations is that historic weapons programmes used anthrax that had been selectively grown to be resistant to antibiotics. Modern next-generation DNA sequencing should allow rapid identification of antibiotic resistance to allow targeted therapy.

The risk of person-to-person transmission of inhalational anthrax is very low. Anthrax is one of a limited number of conditions where there is a significant disease risk from dead bodies as spores may continue to be formed and disseminated from infected bodies if they are not disposed of by incineration at high temperatures in a setting that does not allow for spore release into the atmosphere.

Plague, Tularaemia and Other Diseases

A wide range of other bacterial diseases are of concern, predominantly from diseases where a very low infective dose of bacteria is required to cause infection, where diagnosis may be difficult, or where the risk of person-to-person transmission is high. Although public health measures are likely to be able to control the spread of such infections amongst civilians, from a military context these and other agents have the potential to prevent the free movement of military personnel around a theatre of war constraining military actions. Pneumonic plague, tularaemia, melioidosis and other bacterial pathogens fall into this class. [22] In a deliberate release of such agents, recognition that this is a biological weapon attack will depend on the geopolitical context, particularly if the organism concerned is not endemic to the geographic area affected.

Smallpox

Smallpox or variola is a highly transmissible orthopox virus that was endemic until its eradication in 1978. It was responsible for as many as 400 million deaths in the 20th century. Case fatality rates as high as 30% are reported for smallpox. Populations that had not been exposed to the smallpox virus had very high mortality rates. [23] Smallpox was also a component of historic biological weapon programmes. As this disease has now been eradicated and there are no longer vaccination programmes in civilian populations, public susceptibility is very high. Smallpox is highly transmissible in naïve populations and is disseminated by person-to-person spread, aerosol spread and airborne spread.

The clinical presentation of smallpox is as for other orthopox viruses such as human Mpox; there is a 7–19-day incubation period followed by a period of malaise and then systemic illness followed by oral lesions. This is followed by a vesicular rash, predominantly on the extremities, spreading to the rest of the body. The rash of smallpox differs from that of human Mpox in its distribution and the timing of the lesions. In severely affected patients, death appeared to occur due to pneumonitis and renal involvement, [24] suggesting that modern intensive care might reduce the mortality of smallpox.

Various antiviral treatments such as tecovirimat are available, but the mainstay of management is a combination of public health measures and post-exposure vaccination with identification and vaccination of contacts of recent cases, termed ‘ring vaccination’. Ring vaccination is extremely effective because the prolonged incubation period allows time for the vaccine to work to prevent severe disease.

Other Viral Diseases

Ebola virus disease, Marburg virus, Venezuelan equine encephalitis virus and other highly transmissible or high-consequence infectious diseases are potential biological weapons and some of these were studied by historical state-run biological weapon programmes. Although there is a vaccine available for one of the Ebola virus strains, treatment for most of these viral diseases involves supportive care and public health measures. These conditions are discussed in Chapter 21 .

Biological Toxins

The biological toxins include plant-derived toxins such as ricin and abrin; bacterial toxins including botulinum toxin, staphylococcal enterotoxin B; and a wide variety of other toxins, including mycotoxins from fungi, marine toxins such as saxitoxin and others. These toxins are of concern because many of them are extremely potent. Some of the toxins are denatured by light, heating, hydrolysis and other processes meaning that while theoretically they could be used to injure or kill large numbers of people, the practicalities of this are such that this is unlikely.

Ricin and abrin are plant toxins derived from the castor bean and rosary pea respectively. Ricin has been used in targeted political assassinations and in attempted and actual poisonings. Ricin and abrin are ribosomal poisons, [25] preventing protein transcription. After exposure, cells with rapid turnover are affected and the poisoned patient develops a rapidly progressive systemic inflammatory response followed by multi-organ failure and death. Diagnosis is clinical, though if sampling is carried out early, ricidine may be detectable in the urine by specialised laboratories. A key difficulty when dealing with ricin poisoning is differentiating between this syndrome and sepsis with multi-organ failure. Treatment is supportive. Ricin antitoxins have been researched but are not currently available. [26]

Staphylococcal enterotoxin B is the same toxin implicated in staphylococcal food poisoning and toxic shock syndrome. It was studied in historical biological warfare programmes. It is extremely potent and causes a severe systemic inflammatory response similar to that seen in toxic shock syndrome. [27] If aerosolised it can cause severe eye and respiratory irritation and potentially severe respiratory failure and death. Treatment is supportive.

Botulinum toxin is produced by *Clostridium botulinum* and is one of the most potent toxins with a dose of less than 1 μg potentially being lethal. Botulinum toxin inhibits the release of neurotransmitters at the neuromuscular junction, causing speech and swallowing difficulties and loss of sweating. Prominent bulbar signs develop, followed by a descending paralysis with respiratory failure leading to death without intervention to support ventilation. [28] There is a specific botulinum antitoxin which is used in clinical practice for cases of wound botulism. The antitoxin will inactivate any circulating botulinum toxin but does not have any significant effect on botulinum toxin that has already bound to nerve endings. Recovery from botulinum toxin exposure, as for botulism, may take many months with patients potentially requiring prolonged mechanical ventilation until nerve function recovers.

Fungal mycotoxins [29] cause a range of syndromes, including severe inflammatory responses. There is no specific antidote and treatment is supportive.

Marine toxins such as saxitoxin are used to investigate the physiology of ion channels with extensive published research on many of these toxins. They might theoretically be used as biological weapons due to their potency, but because many of them are complex molecules or combinations of molecules, it is not clear if it would be possible to manufacture them on a large scale.

Radiological Weapons and Nuclear Reactor Incidents

Radiation exposure syndromes can take various forms. Localised burns caused by exposure to industrial or medical radiation sources are treated as for other kinds of burns with the caveat that surgical treatment may require the involvement of a surgeon experienced in treating post-radiotherapy patients as tissue and blood vessels in the affected area are likely to be very friable.

Superficial contamination with radioactive isotopes may cause burns which may range from partial thickness to full thickness. Decontamination and treatment for thermal burns are indicated. Patients with associated acute radiation syndrome may suffer a significant pancytopaenia in the following weeks, and the timing of surgical intervention should take this into account.

Acute radiation syndrome[30,31] is a response to life-threatening radiation exposure and may take the form of haematopoietic syndrome, gastrointestinal syndrome or cardiovascular/neurological syndrome.

Haematopoietic syndrome is bone marrow failure leading to delayed onset of pancytopaenia and consequent bleeding and infection risk. The haematopoietic syndrome occurs across a range of doses of radiation and may be considered to be similar to a post-chemotherapy or radiotherapy syndrome. Patients with lower radiation exposures may survive with treatment with blood products, colony-stimulating factors and anti-infective therapies. It is likely that bone marrow transplantation will be effective in selected patients.[32]

Gastrointestinal syndrome represents severe damage to the intestinal epithelium and includes mucositis, diarrhoea, malabsorption and gastrointestinal bleeding. Cardiovascular syndrome is a manifestation of very high levels of radiation exposure and is characterised by cardiovascular collapse. A neurovascular syndrome can occur after very high doses of radiation with confusion, agitation, seizures, coma and death. Patients with radiation exposure severe enough to cause gastrointestinal, cardiovascular or neurological syndromes are very likely to die.

Early clinical signs may predict major radiation exposure. Patients with acute radiation syndrome experience a prodromal illness with the rapidity of onset and severity predicting outcome to some extent. In milder forms, this may cause anorexia and vomiting, followed by a latent period where the patient is asymptomatic, followed by a manifest illness, then recovery or death.

Sequential white blood cell counts can be used to estimate the severity of radiation exposure using online or published calculators, with an early drop in white cell count denoting severe exposure.

A major consideration in CBRN medicine is the detonation of a radiological dispersal device in a terrorist attack. This so-called ‘dirty bomb’ technique involves using a conventional explosive device to disseminate radioactive material. Various radioactive agents used in industrial and healthcare applications could be used to make such a device. Examples include caesium-137, cobalt-60 or iridium-192. Management of patients injured by one of these devices follows standard paradigms of resuscitation with radiation being a lesser consideration until traumatic injuries are dealt with.

Identification of external contamination is relatively straightforward. In most developed countries the emergency services attending an incident will have either person-worn or portable radiation detectors and would be expected to identify if there has been a radioactive release. Hospital emergency departments should have access to radiation detectors and be trained in their use. Larger hospitals may have radiation physicists who are used to working with radioisotopes and should be incorporated into major incident planning.

External contaminants in the form of radioactive particles or dust from an explosion can be removed by standard decontamination techniques by removal of clothing and skin decontamination using detergent and water. Care should be taken not to aerosolise any residual contamination on clothing and to control any residual water runoff after decontamination, as it is likely to contain radioactive substances.

Internal radiation contamination may be more difficult to identify, particularly with alpha particle emitters such as polonium-210. An example of this was the 2006 assassination of a journalist and former Russian security service officer. [33] The patient was admitted to a hospital in London with gastrointestinal symptoms including diarrhoea and vomiting and subsequently developed the haematopoietic syndrome of bone marrow failure as well as mucositis and alopecia. He then developed multi-organ failure and died in spite of renal, respiratory and cardiovascular support in the intensive care unit. The patient believed it was likely he had been poisoned, but initial toxicology studies did not reveal a likely poison other than a higher-than-normal level of thallium in the urine. Geiger counter screening of his body did not identify any gamma radiation. Subsequent specialised examination of his urine with a gamma ray spectrograph identified that he had been poisoned with polonium-210 which predominantly produces alpha particles. The absence of easily detectable gamma radiation made the diagnosis particularly difficult. Subsequent examination of tissue suggested that the dose of radiation he had ingested was likely to have been lethal even with treatment.

Internal contamination with radioisotopes may be treated with chelating agents such as Prussian blue (potassium hexacyanoferrate) or diethylenetriaminepentaacetic acid (DTPA). Specialist advice will be required from national poison centres or national public health bodies.

Potassium iodide may be given orally in the immediate aftermath of a nuclear reactor accident. [34] It prevents thyroid uptake of radioactive iodine-131 and may protect the thyroid gland from this radioisotope. Potassium iodide may cause transient hypothyroidism, but after a few weeks, most patients should recover from this.

Nuclear Weapons

Nuclear weapon detonation has the potential to cause catastrophic disruption to health services. This needs to be planned for in a civil and military response. It is important to recognise that even a relatively small nuclear explosion in a city is likely to incapacitate and/or kill very large numbers of people and also severely disrupt any ability to provide organised critical care. The expectation is that multiple hospitals in the affected area will be partially or completely destroyed, with injuries and deaths of many health care workers. The electromagnetic and blast effects of the nuclear explosion will destroy electrical grids and backup generators as well as permanently destroying electronic components in most medical equipment in the vicinity of the detonation. Large numbers of patients with burns and blast injuries will be expected, many with unsurvivable injuries. In this scenario, efforts to treat patients may be better focussed on caring for large numbers of displaced people and identifying those with survivable injuries.

A proportion of patients with acute radiation syndrome may respond to treatment with colony-stimulating factors, stem cell transplantation and other advanced haematological treatments, but this will very much depend on how much capacity the health system has to deliver complex interventions after sustaining severe damage to its infrastructure.

Prehospital Decontamination

Specialist prehospital response teams will be expected to have access to air-purifying respirators or self-contained breathing apparatus as well as chemically resistant suits.

Patients should not be brought into the hospital emergency department until they have been decontaminated, preferably at a safe location prior to transport to the hospital. This applies to chemical agents, toxins, biological spores and radioisotopes, but is also of relevance in patients with high-consequence infectious diseases where body fluids may carry transmissible agents.

In severely injured or poisoned patients, only lifesaving interventions such as control of catastrophic haemorrhage, basic airway interventions and administration of antidotes using intramuscular autoinjectors should be carried out prior to decontamination. Prehospital medical and paramedical staff carrying out initial assessment and lifesaving interventions prior to decontamination should wear an appropriate level of personal protective equipment.

Decontamination of patients exposed to chemical or radiological agents is predominantly by removal of clothing, which will remove the majority of the contaminant. This is followed by washing in water with a mild hypochlorite solution or detergent. Even relatively simple decontamination using materials that are readily to hand is fairly effective, for example removing clothing and then scrubbing the skin with tissue paper from rolls carried on ambulances. Emergency services should have the capability of mass decontamination using portable showers for use in major incidents where chemical weapon use is suspected.

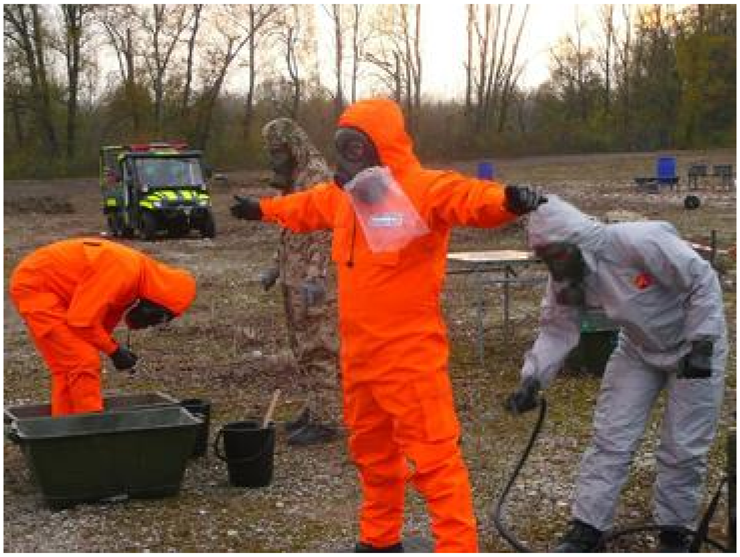
Specialist commercial decontamination agents contained in sponge applicators saturated in detergent with added oxime antidote may be used in military settings.

There is a risk of volatile chemical agents in clothing and on the skin causing poisoning in hospital staff; this is a particular concern with highly potent nerve agents. In military and some specialist police settings, specialist chemical sensor equipment may be available to show that a patient has been completely decontaminated prior to transport to hospital, but these detection capabilities will not detect all chemical agents. Detection for nerve agents, cyanide and sulphur mustard may be available. Emergency services may have the ability to carry out mass spectrography or other analytical techniques at the scene of a major incident which may identify the agent responsible.

There is a risk of internal contamination from radioactive fragments after an explosion, or from inhalation or ingestion of radioisotopes. The risk to healthcare providers from this kind of contamination is expected to be extremely low and medical interventions take precedence over decontamination.

Personal Protective Equipment for Hospital Staff

The specific agent suspected or confirmed to be present informs the requirement for respiratory, face and skin protection and in particular the risk of residual chemical vapour or residue on the patient’s skin (non-volatile nerve agents such as Novichok), the risk of aerosolised or airborne biological agents and the risk of radioactive dust. The lowest level of personal protective equipment needed should be used to limit the burden on staff in terms of thermal stress and the limitations on communication caused by wearing additional layers of clothing and respiratory protection (Fig. 108.1).



The group of four individuals wearing hazmat suits and gas masks is performing decontamination tasks in an outdoor setting. Two individuals are in bright suits, standing with arms outstretched, one of them being sprayed by a person using a hose. Another person bends over near a container filled with liquid. A person in camouflage gear stands behind them.

FIG. 108.1 Members of a UK Hazardous Area Response Team undergoing decontamination during a CBRN exercise.

For most CBRN incidents standard clinical personal protective equipment is sufficient for hospital staff. Specific national guidance exists relevant to the different chemical, biological and radiological threats that may be faced and should be incorporated into hospital major incident plans.[35], [36]

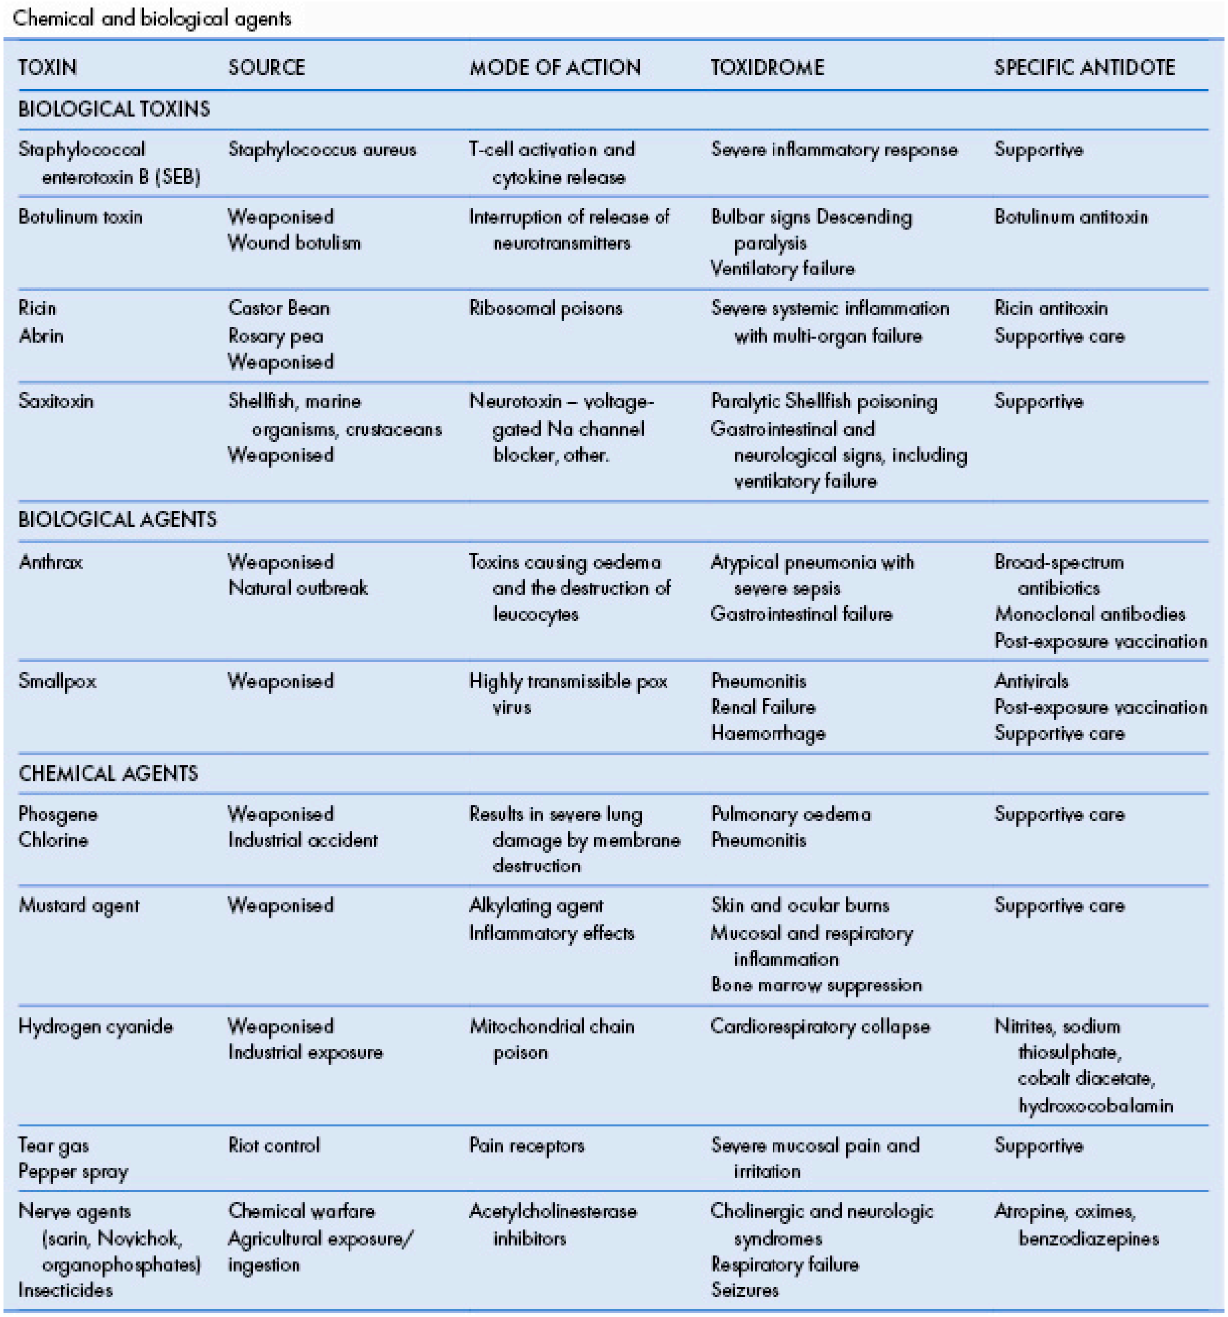
In cases of biological agent exposure, standard clinical infection control processes are appropriate for patients with airborne or aerosolised infections such as SARS-CoV-2. This should include control of clinical waste for safe disposal. If there is a suspicion of exposure to a high-consequence infectious disease such as smallpox or Ebola virus disease, expert advice should be sought.

The Evolving Threat

There are various new weapon systems, including directed energy weapons that use laser or microwave energy to interdict missiles. At present, there is very little published about the medical effects of these weapons and no specific treatment other than supportive care. Blinding laser weapons are banned by international treaties.

Chemical and biological agents in particular are a continuing threat, and step changes in multiple scientific fields are likely to make it easier for rogue states or terrorist organisations to manufacture and use these weapons (Table 108.2).[37] Advances in synthetic biology including the ability to edit the genome with clustered regularly interspaced short palindromic repeats – associated protein 9 (CRISPR-CAS9) and similar technologies mean that generating antibiotic-resistant organisms and altering viral characteristics will almost certainly continue to get easier.

Table 108.2



Chemical and biological agents

TOXIN	SOURCE	MODE OF ACTION	TOXIDROME	SPECIFIC ANTIDOTE
BIOLOGICAL TOXINS				
Staphylococcal enterotoxin B (SEB)	Staphylococcus aureus	T-cell activation and cytokine release	Severe inflammatory response	Supportive
Botulinum toxin	Weaponised Wound botulism	Interruption of release of neurotransmitters	Bulbar signs Descending paralysis Ventilatory failure	Botulinum antitoxin
Ricin Abrin	Castor Bean Rosary pea Weaponised	Ribosomal poisons	Severe systemic inflammation with multi-organ failure	Ricin antitoxin Supportive care
Saxitoxin	Shellfish, marine organisms, crustaceans Weaponised	Neurotoxin – voltage-gated Na channel blocker, other.	Paralytic Shellfish poisoning Gastrointestinal and neurological signs, including ventilatory failure	Supportive
BIOLOGICAL AGENTS				
Anthrax	Weaponised Natural outbreak	Toxins causing oedema and the destruction of leucocytes	Atypical pneumonia with severe sepsis Gastrointestinal failure	Broad-spectrum antibiotics Monoclonal antibodies Post-exposure vaccination
Smallpox	Weaponised	Highly transmissible pox virus	Pneumonitis Renal Failure Haemorrhage	Antivirals Post-exposure vaccination Supportive care
CHEMICAL AGENTS				
Phosgene Chlorine	Weaponised Industrial accident	Results in severe lung damage by membrane destruction	Pulmonary oedema Pneumonitis	Supportive care
Mustard agent	Weaponised	Alkylating agent Inflammatory effects	Skin and ocular burns Mucosal and respiratory inflammation Bone marrow suppression	Supportive care
Hydrogen cyanide	Weaponised Industrial exposure	Mitochondrial chain poison	Cardiorespiratory collapse	Nitrites, sodium thiosulphate, cobalt diacetate, hydroxocobalamin
Tear gas Pepper spray	Riot control	Pain receptors	Severe mucosal pain and irritation	Supportive
Nerve agents (sarin, Novichok, organophosphates) Insecticides	Chemical warfare Agricultural exposure/ ingestion	Acetylcholinesterase inhibitors	Cholinergic and neurologic syndromes Respiratory failure Seizures	Atropine, oximes, benzodiazepines

Fortunately, the same technologies that may allow the development of new threats also have already improved detection capabilities based on rapid and inexpensive next-generation sequencing. [38] In the near future, novel diagnostic techniques for recognising ultra-small quantities of target molecules and genetic sequences are likely to be available.

Novel diagnostic techniques that identify pathogen-associated molecular patterns in near-patient tests, more rapid laboratory microbiologic and virologic diagnostics and antimicrobial resistance identification may well mean that the index cases of a deliberate release are identified in time for public health measures to prevent further spread.

Advances in understanding the cellular pathways involved in inflammation and repair may also deliver agents that can treat radiation syndromes after exposure, an area that is currently a major gap in treating patients exposed to radiation.

Anaphylaxis

Peter Rostron Platt and Paul Harold Martin Sadleir

Definition and Criteria for Diagnosis

Anaphylaxis is an acute multisystem disorder with a variable presentation secondary to the release of multiple mediators from mast cells and, a role less clearly defined, by basophils, neutrophils and platelets. Since its original description and invention of the term ‘anaphylaxis’ by Charles Richet (Nobel Laureate 1913) [1] and later the recognition of a new immunoglobulin, IgE in 1968, the term anaphylaxis has been generally used specifically for an acute hypersensitivity reaction to a foreign substance mediated by IgE. With the recognition that the mast cell could be triggered to release mediators via other mechanisms producing an identical pathophysiological syndrome, the collective term ‘ *anaphylactoid’* was coined to distinguish these reactions from those mediated by IgE. Using anaphylaxis guidelines published in 2010 by major allergy/immunology organisations, [2–4] the World Allergy Organisation (WAO) aligned these guidelines. [5] Importantly, it was agreed that a diagnosis of anaphylaxis should be based on symptoms and signs as defined by Sampson et al. in 2006 [6] (Table 109.1). These clinical criteria may be limited to signs in the sedated or anaesthetised patient in the critical care environment; hypotension that is relatively unresponsive to vasopressors may be the only warning sign of anaphylaxis in these settings. The WAO recommended abandonment of the terms *anaphylactoid* and *pseudo-allergy* to describe non-IgE–mediated reactions. They redefined *anaphylaxis* as ‘a serious, life-threatening generalised or systemic hypersensitivity reaction’ that may be *immune-mediated* (IgE or non-IgE) or *non-immune mediated* , although this has not been met with universal agreement. The pathophysiological mechanisms of anaphylaxis are discussed in detail below, with particular emphasis on the most prevalent immunological, IgE-dependent mechanism. Immunological non-IgE mechanisms including complement activation and activation of the kallikrein-kinin contact system are discussed in the section detailing representative agents. Non-immunological mechanisms include direct activation of the only recently identified Mas-related G-protein coupled receptor member X2 (MRGPRX2) [7] responsible for histamine release caused by drugs such as opioids. Physical factors such as exercise, cold and heat can co-contribute as causes of anaphylaxis and those that are unexplained are classified as idiopathic.

Table 109.1

[a] Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year, less than (70 mm Hg + (2 × age)) from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years.

BP , Blood pressure; *PEF* , peak expiratory flow.

Modified from Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report – second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol* . 2006;117:391–397.

Epidemiology

Estimates of incidence rates of anaphylaxis are widely variable around 10–20 per 100,000 population. Less than one-third of these patients will require hospital admission. In the United Kingdom between 1992 and 2012, hospital admissions [8] increased by 615% and critical care admissions between 2005 and 2009 almost doubled [9] but annual fatality rates remained stable at 0.047 cases per 100,000 population. In contrast, Australian total hospital admissions for anaphylaxis increased almost fourfold and fatal anaphylaxis almost doubled in the period 1997–2013. [10] Although anaphylaxis is a potentially lethal condition, it only accounts for a small proportion of the workload of critical care units. Motosue et al. reporting on 38,695 emergency department admissions for anaphylaxis in the United

States, noted that 5.3% required ICU admission, 1.5% required intubation and only 0.45% were considered as having a near-fatal episode. [11]

Risk Factors

Anaphylaxis may be associated with a number of risk factors that can increase the severity, risk of fatality and decreased response to treatment. Refractory anaphylaxis is descriptive for severe cases of anaphylaxis unresponsive to two doses of adrenaline. The largest number of incident cases of anaphylaxis is in children but it is teenagers with food allergies and poorly controlled asthma that are at risk of critical bronchospasm with rapidly developing hypoxia, cerebral injury and brain death. Increasing age and co-morbidities such as coronary artery disease or hypertension, particularly if treated with beta-blockers and/or angiotensin-converting enzyme (ACE) inhibitors, are associated with unresponsiveness to treatment, hospitalisation and increased fatality. Systemic mastocytosis (SM) and other variants of mast cell activation disorders are often only recognised after unexpectedly severe reactions to insect stings or drugs. Drug-induced anaphylaxis, when the allergen is given intravenously, most notably with antibiotics and neuromuscular blocking drugs in the perioperative setting, is often refractory and is the most common cause of death during surgery caused solely by anaesthesia.

Pathophysiology of Anaphylaxis

Mast cells and to a lesser extent basophils, platelets and neutrophils release mediators such as histamine that are responsible for the physiological changes seen during anaphylaxis. The commonest molecular mechanism responsible for anaphylaxis is the classic allergic IgE-mediated pathway but other endotypes are recognised that can be divided into other *immune-mediated* (IgG dependent, complement activation and cytokine release reactions) and *non-immune-mediated* pathways such as via MRGPRX2 receptors. [12] Mast cells are found in the tissues and basophils in the circulation. Both have high-affinity receptors (FcεRI) on their surfaces. Binding of an allergen to adjacent FcεRI/antibody complexes, ‘cross-linking', will lead to a sequence of signalling events resulting in mediator release from the mast cell or basophil; however, this is not all or none, maximal stimulation will only release 10%–20% of stored mediators. A minimum number of cross-linking events, between 100 and 1000, are required for any degree of release. [13]

Mediator Release

After full activation of the FcεRI and maintenance of the receptor complex for as little as 100 seconds, there is transduction of intracellular signals that lead to the release of pre-synthesised mediators such as histamine, serotonin, various proteases such as tryptase, carboxypeptidases and other enzymes contained in granular stores. [14] These, particularly histamine, are responsible for the immediate cardiovascular, respiratory and skin changes that are seen at the onset of anaphylaxis. Phospholipid metabolites are the second group of mediators, generated as a consequence of the release of phospholipaseA_2, such as platelet-activating factor (PAF) and the eicosanoids PGD_2, LTC_4 and LTB_4 that individually can have physiological consequences such as bronchospasm and local or generalised angioedema. Enhanced gene expression leads to the generation of the third group of mediators, the cytokines and chemokines that are responsible for cell signalling and chemotaxis. [15] The physiological response results from the complex interaction of these multiple mediators with their individual receptors and thus may be variable in duration, intensity and clinical features.

FcεRI engagement also generates negative intracellular signals that limit the duration and intensity of the release process and also triggers endocytosis of the activated complexes, thus removing them from the cell surface and terminating the response.

The Physiological Response to Mediator Release

In a setting of patient heterogeneity, complex mediator release mechanisms and different triggers, the physiological response is unpredictable in both the individual organ and in overall severity.

Skin Changes During Anaphylaxis

Skin eruptions are the most consistent feature of anaphylaxis, although their absence does not exclude the condition and generalised erythema may frequently not manifest until after resolution of haemodynamic instability. In anaphylaxis, both urticaria (pruritic raised patchy erythematous lesions) and angioedema (swelling of the deeper dermis and subcutaneous tissues and may also involve mucosal surfaces) are frequent, and usually the consequence of IgE-dependent activation of cutaneous mast cells resulting in increased vascular permeability which is predominantly a consequence of activation of H1 histamine receptors. Nervous system stimulation, axonal reflexes and other mediators, such as tryptase, cytokines and chemokines may play a role in amplifying the reaction.

Respiratory Changes During Anaphylaxis

Respiratory manifestations of anaphylaxis may involve the lower airway (dyspnoea, bronchospasm and hypoxaemia) or upper airway (stridor or upper airway obstruction, tongue swelling, dysphonia or dysphagia and rhinitis). Mast cell-derived mediators cause vasodilatation, smooth muscle contraction and mucus secretion in the nasal and bronchial mucosa. Autopsy findings in cases of fatal anaphylaxis include pulmonary oedema, laryngeal and/or pharyngeal oedema, lung hyperinflation and mucous plugging (suggesting bronchospasm and air-trapping) and evidence of asphyxiation (petechial haemorrhages). Upper airway oedema or obstruction is more common in food allergies compared to medication-triggered anaphylaxis.

Anaphylaxis during surgery and anaesthesia is commonly associated with mild increases in airway pressure and severe bronchospasm is rare except in patients with a history of increased airway responsiveness such as in asthma, smoking and other conditions associated with chronic airflow limitation. There are rare reports of bronchospasm being the only presenting feature.

Cardiovascular Changes During Anaphylaxis

From clinical observations of anaphylaxis under anaesthesia Fisher found the most common manifestation was cardiovascular depression characterised by profound hypotension, sinus tachycardia, loss into the interstitial space of up to 35% of blood volume and low cardiac filling pressures. [16] Although simplistic, it is not unreasonable to regard histamine as the principal mediator that is responsible for the initial cardiovascular effects. [17], [18]

Peripheral Vasculature

Hypotension occurs not only as a result of a fall in systemic vascular resistance but also because of failure of venous return due to both interstitial loss and sequestration of blood in the peripheral venous systems. Vasopressors, essential to increase systemic vascular resistance, will be ineffectual on their own unless the cardiac output is maintained by volume repletion. Having studied details of 214 deaths associated with anaphylaxis, Pumphrey in 2003 reported a striking pattern of sudden death after a change to an upright posture in 10 of 38 anaphylactic shock deaths that occurred outside hospital. [19] He described a mechanism based on the lack of venous return to explain this phenomenon. He went on to express the importance of the recumbent position with legs raised in first aid of shocked patients and explained why epinephrine can be ineffective in these patients. The benefit of posture has also been echoed by Brown [20] in the emergency medicine setting, as has the benefit of the pneumatic antishock garment or MAST suit. [21] The importance of venous capacitance has largely been forgotten or ignored in discussions of circulatory changes during anaphylactic shock, although the relationship between venous capacitance and cardiac output is well described. [22], [23]

The Splanchnic Circulation

About 25% of total blood volume resides in the splanchnic venous vasculature a significant proportion of which can be transferred to the systemic circulation with sympathetic stimulation. Paradoxically, in many animal species, anaphylaxis causes hepatic vein constriction with the entrapment of blood in the portal circulation causing a reduced venous return to the heart, dramatic increases in portal pressure, gut oedema and necrosis of the epithelium and death of the animal. [24] Oedema of the gall bladder wall, evidenced as the Halo sign on ultrasound, is pathognomic of anaphylaxis in dogs. Although abdominal pain and diarrhoea are commonly associated with anaphylaxis in men and oedema of the small bowel has been reported on CT scans, the implications of hepatic vein obstruction during anaphylaxis, have not been determined in men. If it were so the loss of blood from the systemic circulation would compound the effect of volume loss into the interstitial space, explaining the failure of venous return, commonly under-recognised in severe anaphylaxis, and the importance of adequate volume resuscitation.

The Heart

The use of echocardiography during anaphylaxis characteristically shows a hyperdynamic but empty heart. [25], [26] Rarely, Takotsubo cardiomyopathy [27] may occur that may be the result of either intense endogenous catecholamine release or excessive use of epinephrine. The electrocardiogram may show changes consistent with ischaemia and cardiac enzymes may be elevated with angiographically normal coronary arteries.

Allergic events may be associated with angina and angiographic evidence of coronary spasm in both adults and rarely children and also with atheromatous plaque erosion or rupture, causing myocardial infarction. This association between acute allergic reactions and coronary events is known as Kounis syndrome. [28]

Causes of Anaphylaxis

Food

Almost 10% of the population of developed countries have a food allergy with one-third being severe. [29] Almost any food may be responsible for allergy, but only eight food groups account for 90% of food-related allergies; peanuts, tree nuts, fish and crustacea often persist into adulthood, whereas milk, egg, wheat and soy often resolve before the teens. Food allergy is responsible for almost all allergic hospital admissions in the under-4-year-old age group and most fatalities in teenagers, particularly when associated with asthma. By middle age, food-related allergies are relatively uncommon as a cause of hospital admissions and fatalities compared to those due to drug and insect stings. Latex allergy can be associated with cross-reactivity to fruits including avocado, banana, chestnut, kiwifruit and papaya. Food-associated, exercise-induced anaphylaxis can occur when an otherwise harmless food is consumed 2–4 hours before exercise.

Drugs

Drug-Induced Anaphylaxis (DIA)

The prevalence of DIA to a specific drug in a population is determined by rates of exposure and underlying hypersensitivity. Hence, population-based surveys from different countries or jurisdictions may disagree on the incidences of anaphylaxis. In the ambulatory setting, NSAIDS and antibiotics predominate, with the latter more often severe. In-hospital surveys implicate drugs and agents used in the perioperative setting, particularly prophylactic antibiotics, chlorhexidine and neuromuscular blocking drugs (NMBD). Recently, studies from France and Western Australia have convincingly demonstrated that pholcodine-containing antitussive preparations are responsible for sensitisation to NMBD, resulting in their withdrawal from markets in the European Union and Australia.[30, 31]

DIA is more frequently associated with cardiovascular effects, is often refractory to therapy, requires intensive care admission and is the commonest cause of fatalities.

A non-exhaustive summary of drugs associated with DIA can be found in Table 109.2 .

Table 109.2

Leading drug and excipient causes of anaphylaxis

DRUG GROUP	CLASS	DRUG	MECHANISM/ COMMENT
Antibiotics	Beta lactams	Amoxicillin ± clavulanic acid ephazolin	Mainly IgE mediated. Commonly used for surgical prophylaxis. Commonest cause of perioperative anaphylaxis
	Glycopeptides	Teicoplanin Vancomycin	Alternatives for prophylaxis in penicillin allergic patients. Vancomycin is a potent MRGPRX2 agonist-> Red Man Syndrome. Rarely IgE-mediated
	Fluoroquinolones	e.g. levofloxacin, ciprofloxacin	Classical mast cell activation via MRGPRX2
	Sulphonamides	Sulfamethoxazole, sulfasalazine	Common cause of allergic reactions. Food preservative 'sulfites' are associated with intolerance, rarely allergy. Sulfonamide allergy does not preclude the use of drugs with a sulfur moiety e.g. frusemide, parecoxib and acetazolimide
Anti-inflammatory Minor analgesic Antipyretics	NSAIDS	Ibuprofen and diclofenac are leading NSAID triggers	Selective Responders have IgE-mediated reactions to a single NSAID. Alternatively, many patients express cross-intolerance across the group mainly via Cox1 inhibition, causing NSAID-exacerbated respiratory disease and urticaria/angioedema
		Mefenamic acid	
		Aspirin, paracetamol, pyrazalones	
Neuromuscular Blocking Drugs (NMBD)	Non-depolarising amino-steroids	Rocuronium, vecuronium	Cross-reactivity is unpredictable and common both within and across groups. IgE mediated, often severe. Common cause of in-hospital anaphylaxis requiring ICU admission
	Non-depolarising benzylisoquinolines	Atracurium, mivacurium, cisatracurium	Histamine release via MRGPRX2 related to dose and rate of injection. Less commonly IgE mediated
	Depolarising	Suxamethonium	Rapid onset of paralysis; commonly used for emergency intubations. Highest risk of anaphylaxis in this drug group per administration
Iodinated products	Iodinated contrast media. (ICM)	Mild immediate reactions related to physical properties such as high osmolality and potential for dissociation into charged ions in solution. Rarely IgE mediated, then severe	
	Povidone iodine	Skin antiseptic. Hypersensitivity specific to povidone and not iodine thus no cross-sensitivity with ICM	
Others	Chlorhexidine (Cx)	Widespread exposure and sensitisation in hospital and community. Common cause of perioperative and in-hospital anaphylaxis. Internalisation of Cx via coated central venous lines, wound washout, swabbing intravenous access ports and Cx containing urinary catheter local anaesthetic lubricants increases risk	
	Protamine	Multiple mechanisms from mild MRGPRX2 mediated to anaphylaxis via IgE mechanism. Heparin/protamine complexes via complement activation and release of thromboxane in the pulmonary circulation causing pulmonary hypertension and severe right-sided heart failure	
	Angiotensin-converting enzyme inhibitors (ACEIs)	Cause spontaneous tongue and laryngopharyngeal angioedema causing critical airway obstruction. Important to differentiate it from Ige-mediated because bradykinin-induced oedema does not respond to antihistamines, epinephrine or steroids. Treatments approved for hereditary angioedema; icatibant, ecallantide, fresh frozen plasma and C1-INH are appropriate treatments for ACEI-AAE	
Pharmaceutical excipients[32]	Polyvinylpyrrolidone (PVP/Povidone)	Common polymer vehicle in many medications and agents including povidone iodine and some brands of intravenous paracetamol	
	Polyethylene glycols (PEGs) Alternate name Macrogols	Depot steroid preparations, erythropoietin, laxatives, Covid-19 vaccinations bone cement and many others	

Gelatin-Based Colloids, Meat and Cetuximab

Although seemingly unrelated, these three causes of anaphylaxis have the oligosaccharide galactose-alpha-1,3-galactose (alpha-gal) in common. This sugar is common to all mammals except the higher primates, including humans. With both gelatin-based colloid and Cetuximab (Erbitux, Bristol-Myers Squibb and ImClone Systems), acute hypersensitivity reactions occurred on first exposure, raising speculation as to the sensitisation process. In the late 2000s, reports from the United States, Sweden and Australia clarified the association between ticks, delayed anaphylaxis after the ingestion of red meat [33] and anaphylaxis after initial exposure to Cetuximab, [34] a chimeric mouse-human IgG1 monoclonal antibody used in the treatment of colorectal cancer and squamous-cell cancers of the head and neck. In these patients, pre-existing antibodies to alpha-gal were identified in the serum, the generation of which was sensitisation by exposure to tick bites. The alpha-gal is transferred from the host mammal to the human with the resultant production of antibodies that are specific for the alpha-gal present in gelatin, Cetuximab and meat.

With the recognition of complications associated with the use of starch-based colloids in critically ill patients, gelatin-based [35] colloids have had a resurgence but also an increased risk of anaphylaxis. This should be considered as a greater risk in patients allergic to red meat and in tick-prone areas, although the pathogenic relationship, as yet, is not fully elucidated.

Intraoperative anaphylaxis may be caused by Floseal Haemostatic Matrix (Baxter Healthcare Co., Hayward, California), a topical haemostatic agent containing bovine-derived gelatin. Other gelatin-containing haemostatic agents such as Gelfoam (Pfizer, New York) and SurgiFlo (Ethicon, Somerville, New Jersey) have also been implicated.

Blood Products

Anaphylaxis occurs in 1:20,000–1:50,000 whole blood transfusions. The mechanisms implicated include (1) IgA-deficient recipients who have anti-IgA antibodies, (2) transfusing an allergen in the donor blood such as penicillin or nuts to a sensitised recipient, (3) recipient with antibodies to plasma proteins such as transferrin or IgG and less commonly (4) transfusion of IgE antibody from the donor that reacts with an allergen in the recipient. A haemolytic transfusion reaction should be considered in the differential diagnosis.

Latex

In the 1980s, coincident with, and in part due to, the human immunodeficiency virus epidemic, latex allergy became a major health issue. Massive demand for latex gloves resulted in the production of a low-quality, highly allergenic product leading to widespread sensitisation, particularly of workers in the health care setting. The use of cornstarch in powdered gloves resulted in an effective means of dispersion of airborne latex particles into the hospital environment, particularly the operating room. Of the greater than 200 polypeptides occurring in natural rubber latex (NRL), 13 are the primary allergens (Hevea braziliensis [Hev b] 1–13), which induce antibody formation detectable by specific IgE testing. In the late 90s, Mertes[36] reported latex as the second most common cause of perioperative anaphylaxis in France (16.7%); this incidence has not fallen but has not been reported as being so common elsewhere. Surgery in infancy, particularly spina bifida which often requires multiple surgeries and catheterisations, was responsible for greater than 75% of anaphylaxis cases in children. With the introduction of better quality control in the manufacture of low-allergenic gloves, the discontinuation of powder and the adoption of latex-free policies in the healthcare environment, both sensitisation and anaphylaxis rates have fallen significantly.

Anaphylatoxins

The anaphylatoxins C3a, C4a and C5a are produced on activation of the complement system and act on a group of G-protein coupled anaphylatoxin receptors. This pathway is an alternative to the IgE pathway of mast cell activation with resultant mediator release and clinical syndrome of anaphylaxis.

In early 2008 many severe adverse events were reported worldwide associated with heparin therapy, including over 100 deaths in North America. Subsequent investigation identified a highly sulphated heparin-like contaminant – oversulphated chondroitin sulphate (OSCS) as the cause.[37] The associated activation of the kinin-kallikrein system with formation of bradykinin enhanced the hypotensive response.

Polyethoxylated castor oil has been used widely in the formulation of poorly water-soluble drugs such as the anticancer agent paclitaxel, intravenous multivitamin preparations, early formulations of propofol and diazepam and the obsolete anaesthetic induction agents Althesin and Propanidid. There have been several mechanisms of activation of anaphylaxis linked to this agent, including direct histamine release, IgE, IgG and complement.

MAST Cell Disorders

The descriptions mentioned previously relate to normal populations of mast cells. There are a number of disorders of mast cells associated with abnormal proliferation or increased susceptibility to activation. [38]

Systemic mastocytosis (SM) is a condition associated with a mutation of the tyrosine kinase receptor c-KIT that results in both increased numbers and aberrant activation of mast cells. Such patients may have variable symptoms attributable to mast cell activation or may present with particularly severe anaphylaxis to Hymenoptera stings. Skin lesions, typically urticaria pigmentosa, are present in most cases. A baseline mast cell tryptase (MCT) over 20 ng/mL is consistent with a diagnosis of SM. The primary diagnostic feature is the finding of multifocal mast cell clusters of atypical morphology in bone marrow.

Monoclonal mast cell activation syndrome (MMAS) presents with the same symptoms as SM and is associated with a KIT mutation and abnormal mast cell clones but the baseline tryptase is normal. There are no skin changes and atypical cell clusters in the bone marrow are sparse or absent.

Non-clonal mast cell activation syndrome (nc-MCAS) has a similar clinical presentation to MMAS but no atypical clonal mast cells or evidence of KIT mutation. It is possible, but not proven, that the increased susceptibility to activation is due to an intrinsic defect in the mast cell causing increased sensitivity to activation.

Surgery, anaesthesia and the critical care environment are associated with anxiety, stress, pain and exposure to innumerable drugs that may trigger the susceptible mast cells in these conditions. Perioperative management [39] of patients can be achieved successfully with mast cell stabilising drugs and the avoidance of opioids and muscle relaxants that have histamine-releasing properties.

Laboratory Tests

MAST Cell Tryptase

The principal effector cell of anaphylaxis from whatever cause is the mast cell with, as yet, incompletely defined contributions from the basophil. There are assays of many of the mediators released from the mast cell on degranulation but most of these are only available in research laboratories. The only useful widely available laboratory test to aid in the clinical diagnosis of anaphylaxis is MCT. [40] Immature forms of tryptase, alpha- and beta-protryptase, that are secreted in small amounts from the unstimulated mast cell account for a baseline level in plasma with a range of 1–11.4 ng/mL. This level is determined genetically and in any one individual varies little over time. Mature tryptase in significant amounts is only detected in the plasma after degranulation. In disorders in which there is an increase in the mast cell population such as the various forms of mastocytosis, baseline levels of protryptase may be elevated. ImmunoCAP tryptase (Thermo Fisher Scientific, Uppsala, Sweden) is widely available in commercial laboratories and measures both immature and mature forms. Any elevation over the upper limit of the reference range in the clinical setting of suspected anaphylaxis is considered diagnostic if the baseline level (measured either prior or 24 hours post event) is in the normal range. Peak levels of tryptase are seen 15–120 minutes after the onset of the reaction with a decline determined by the biological half-life of about 2 hours. If tryptase is still elevated after 24 hours, it should be repeated weeks later; if still elevated, mastocytosis or a haematological neoplasm should be suspected. In severe anaphylactic events, MCT levels greater than 300 ng/mL are not uncommon. In as many as one-third of perioperative, food or insect sting anaphylaxis, MCT may not be elevated above 11.4 ng/mL. Baseline tryptase varies little and if the peak level after a suspected episode of mast cell degranulation is greater than 20% above baseline plus 2 ng/mL, it would be suspicious. Thus a relatively small rise of MCT from 5–8 ng/mL may be of significance. Optimal timing of the recommended three blood samples for MCT is 1, 4 and 24 hours after the initiation of the event. Activation limited to basophils may be rarely responsible for anaphylaxis, in which case the tryptase level would not rise. When anaphylaxis is suspected as a cause of death, a postmortem blood sample may aid in the diagnosis, although significant elevations have been reported with other causes such as cardiac or trauma.

Grading of Anaphylaxis

Ring and Messmer [41] classified hypersensitivity reactions to colloid volume substitutes into four grades based on the severity of symptoms and signs in 1977 (see Table 109.3). This classification system has been used with only minor modifications to describe the severity of immediate hypersensitivity reactions to all food-, environmental- and drug-induced allergens since. Its great success has been the ability to classify both IgE- and non-IgE-mediated reactions and reactions that do not meet the ‘life-threatening’ criterion required for anaphylaxis. In 2004, Brown [42] proposed a classification system (see Table 109.4) in which the discriminating features of the two grades representing anaphylaxis were identified by retrospective analysis of cases to determine which were highly correlated with hypotension and hypoxia (grade 3) or only less closely associated (grade 2). The majority of cases that will require review by intensive care staff are likely to fall into Brown’s grade 3. Additional classification systems have been developed for the signs of intraoperative anaphylaxis; however, none have been demonstrated to be more effective in guiding management or predicting outcomes than Ring and Messmer, and some omit cases of immediate hypersensitivity in which early intervention has prevented progression to anaphylaxis (see Table 109.4).

Treatment of Anaphylaxis

Anaphylaxis is a hyperacute syndrome that may rapidly progress to respiratory or cardiac arrest and death. Early signs and symptoms may have a wide differential diagnosis, and indeed anaphylaxis may be a retrospective diagnosis (indicated by the MCT). Simultaneous assessment and resuscitation should begin immediately. The natural history of anaphylaxis is that it is a temporary condition that will resolve if the patient can be sustained for the period required to allow it do so. Overall, life-threatening respiratory symptoms are more common than lethal cardiovascular derangement, although cardiovascular collapse is more common in iatrogenic medication reactions.[43] Priorities in the initial management are the early administration of epinephrine, rapid administration of intravenous fluids to correct hypovolaemic/maldistributive shock and aggressive management of threatened or established respiratory failure from reduced airway compliance (bronchospasm) or upper airway obstruction (Table 109.5).

Table 109.5

Drug doses for life-threatening anaphylaxis

DRUG	ADULT	CHILD (20 KG)
Epinephrine (IM; 1:1000)	500 µg	0.01 mg/kg (200 µg)
Epinephrine (IV)	50–100 µg initial dose; 0.1–1 µg/kg per minute infusion	Bolus not recommended 0.1–1 µg/kg per minute infusion
Norepinephrine	0.1–1 µg/kg per minute infusion	0.1–1 µg/kg per minute infusion
Vasopressin	2-unit bolus, infusion 0.03–0.06 U/min	0.0001–0.0003 UI/kg per minute [44]
Methylene Blue	2 mg/kg over 20 min	2 mg/kg over 20 min
Glucagon	1–5 mg IV; 5–15 µg/min infusion	20–30 µg/kg up to 1 mg; 5–15 µg/min
Aminophylline	5.6 mg/kg over 20 min	5.6 mg/kg over 20 min
Methylprednisolone	1–2 mg/kg	1–2 mg/kg
Diphenhydramine	25–50 mg IV	1 mg/kg IV
Ranitidine	50 mg IV	1 mg/kg IV
Icatibant	30 µg sc injection (max 90 µg/d)	N/A

IM , Intramuscular; *IV* , intravenous.

General Measures

Management of a patient with suspected anaphylaxis should include the mobilisation of a resuscitation team, application of supplemental oxygen, and establishment of intravenous access (14–16 g). The patient should be placed supine or in the Trendelenburg position with the legs above the level of the heart. Sudden death has been described on adoption of an erect posture in anaphylaxis, of importance when considering elevation of the torso if respiratory distress is present. Pregnant patients should be placed in the left lateral position or with partial left uterine tilt. Electrocardiography monitoring, pulse oximetry and non-invasive blood pressure monitoring should be applied to all patients. In the presence of cardiovascular shock, intra-arterial blood pressure monitoring allows rapid detection of deterioration and titration of therapy as well as the ability to take blood samples for gas and acid-base analysis. Central venous access is also useful for administering vasopressor and inotropic agents and grossly assessing response to volume expansion. Neither should delay the immediate management of presumed anaphylaxis.

Airway and Breathing

A rapid assessment of the patency of the airway should include an examination of the upper airway for evidence of oedema. Early intubation should be considered in patients who develop stridor, hoarseness, difficulty swallowing or significant facial or tongue oedema. The first-line treatment for both upper airway obstruction and bronchospasm in anaphylaxis is systemic epinephrine. Therapeutic effects include bronchodilatation, reduced upper airway mucosal oedema and reduced mast cell and basophil mediator release. Upper airway or external neck landmarks may be distorted due to oedema. Endotracheal intubation and induction of anaesthesia in this situation are likely to be difficult and require the availability of, and familiarity with, difficult intubation adjuncts including flexible fibreoptic bronchoscope, videolaryngoscopy or surgical cricothyroidotomy.

Severe bronchospasms not responsive to intravenous epinephrine should be treated according to the guidelines for the management of acute asthma.

Circulation

Epinephrine is the first-line treatment. Sinus tachycardia is a common feature of anaphylaxis and should not discourage its use. In the absence of significant cardiovascular derangement, intramuscular epinephrine is commonly administered. The adult dose is 500 μg repeated at 5-minute intervals based on response. An epinephrine autoinjector for intramuscular use contains 0.15 mg (for children over 10 kg) or 0.3 mg (for children over 30 kg) to administer the paediatric dose of approximately 0.01 mg/kg. Intravenous epinephrine is preferred in the presence of severe hypotension as the intramuscular route has unpredictable absorption. [45] An initial dose of 50–100 μg IV, followed by incremental increases in the bolus dose or infusion titrated to response, is recommended. Human epidemiological and therapeutic animal studies suggest that delayed or inadequate administration of epinephrine increases the likelihood of fatal anaphylaxis. Therapeutic effects include vasoconstriction and increased peripheral vascular resistance, decreased venous capacitance and increased myocardial contractility (as well as increased coronary blood flow due to an increased diastolic:systolic time ratio and coronary vasodilatation).

Intravenous fluids should be administered with an initial rapid bolus of 20 mL/kg of crystalloid. Effective resuscitation of anaphylactic shock may require up to 50 mL/kg in the first 15 minutes to maintain cardiac preload. [25] Positive-pressure ventilation with a high mean intrathoracic pressure or inadequate expiratory time resulting in the development of significant auto-positive-end-expiratory pressure may impede venous return.

If cardiovascular shock has not responded to intravenous fluids (50 mL/kg in the first 15 minutes) and epinephrine boluses (total 2 mg) and subsequent infusion (e.g. up to 40 μg/min), further management is best guided by immediate transthoracic or transoesophageal echocardiography. This will distinguish insufficient fluid resuscitation (low left ventricular [LV] end-diastolic diameter) from vasoplegia (low LV end-systolic diameter with reasonable LV end-diastolic diameter), pump failure (poor cardiac contractility) or acute pulmonary hypertension (with right ventricular failure). It is also useful in the assessment of Kounis syndrome (acute ST-elevation during anaphylaxis). Regional wall motion abnormalities with ST-segment changes may require angiography with coronary intervention to exclude or treat plaque rupture or coronary vasospasm.

Typical echocardiography findings in anaphylactic shock are the finding of a left ventricle that is hyperdynamic with a low end-systolic diameter, with or without reduced end-diastolic diameter depending on the adequacy of volume resuscitation. If non-responsive to epinephrine, consideration should be given to a norepinephrine infusion, followed by nonadrenergic vasopressors such as vasopressin (initial adult dose 2–4 units IV, followed by infusion). [46] Other agents used in non-responsive shock include methylene blue (2 mg/kg over 20 minutes followed by infusion) or glucagon (1–5 mg IV).

Pulseless electrical activity or asystole occurs in up to 20% of cases of intraoperative anaphylaxis. Contrary to expectations, external chest compressions have been observed to produce an effective arterial waveform during anaphylaxis, and the neurological-deficit-free survival from grade 4 intraoperative anaphylaxis is over 95%. Good outcomes have been observed in patients after prolonged resuscitations (over 60 minutes) and resuscitative attempts should proceed for longer than is usual for cardiac arrest as a result of other pathophysiological conditions.

Extracorporeal Membrane Oxygenation

The presence of significant pump failure (poor cardiac contractility) in resuscitated anaphylactic shock is an indication of veno-arterial extracorporeal membrane oxygenation (VA ECMO) support. This has been described as an effective therapy in multiple case reports. Effective circuit flows may be difficult to achieve in the presence of maldistributive-hypovolaemic shock due to poor venous drainage, although echocardiography-guided resuscitation should allow this to be rapidly corrected. Successful use of VA ECMO will allow time for the resolution of anaphylaxis or reversal of the conditions that caused secondary cardiac decompensation.

ECMO does have a significant iatrogenic complication rate, and side effects of ECMO therapy may be synergistic with the features of anaphylaxis (low venous pressures, oedema, bleeding diathesis), increasing the complication rate from cannulation or circuit operation. VA ECMO in refractory anaphylactic shock in the absence of intrinsic cardiac pump failure is also likely to be problematic. If the cause of refractory shock is low afterload, then it may be that peripheral VA ECMO circuit flows are still insufficient to produce adequate systemic arterial pressure. Significant cardiac ejection may also occur in this situation and result in upper-body hypoxaemia in the presence of pulmonary dysfunction or underventilation and the use of peripheral arterial (return) cannulation ECMO configurations.

The use of veno-venous ECMO support in bronchospasm secondary to anaphylaxis has the same indications and considerations as that which apply to the use of ECMO in severe acute asthma.

Supplemental Management

Antihistamines

Patients with immediate hypersensitivity who do not have life-threatening signs may be administered antihistamines, which are an effective treatment for skin (urticarial and pruritic), gastrointestinal and mild respiratory symptoms (rhinorrhea). A combination of H1 (diphenhydramine) and H2 (ranitidine) antagonists is most effective; however, neither is recommended in severe reactions due to the exacerbation of hypotension, sedation or QT-interval prolongation associated with intravenous administration. Antihistamines should not delay or replace the use of epinephrine in anaphylaxis and are generally omitted in guidelines for the management of life-threatening anaphylaxis.

Corticosteroids

Corticosteroids will not alter the course of the acute reaction in anaphylaxis. Their administration is thought to possibly prevent prolonged anaphylaxis or biphasic reactions. It is also a reasonable intervention in patients with bronchospasm or a history of asthma.

Glucagon

As patients who are currently taking beta-adrenergic blocking agents have been observed to have a poorer outcome in anaphylaxis, the traditional treatment for beta-blocker overdose is suggested. However, it is unclear if excess mortality is a consequence of beta-blocker therapy or the co-morbidities associated with its prescription.

Non-Allergic Angioedema

Angioedema without urticaria can occur in patients taking ACEIs or in patients with inherited or acquired C1-esterase inhibitor deficiency that should not be confused with anaphylaxis. Although the first-line therapy for acute allergic angioedema involving the airways is antihistamines, corticosteroids and epinephrine, this is likely to be ineffective in these patients in which the angioedema may be at least partly mediated by excess bradykinin. Specific treatments for non-histaminergic angioedema include a bradykinin receptor antagonist (icatibant), a plasma kallikrein inhibitor (ecallantide) or an antifibrinolytic agent (tranexamic acid). For suspected hereditary or acquired C1-esterase deficiency, a purified C1-esterase inhibitor may be indicated.

Removing the Trigger

Anaphylaxis results from the interaction between the patient and the environment; however, the dose-response curve of IgE-mediated phenomena is such that many allergen exposures causing anaphylaxis are supramaximal doses. Anaphylaxis also represents the consequences of activation of an amplification-cascade sequence of neurological and hormonal events. As such, once the response to a supramaximal dose of allergen is detected (anaphylaxis), the process is now possibly independent of the initial mast cell degranulation trigger. Although removal of the triggering allergen is an important part of managing anaphylaxis it may be impossible such as after intravenous injection of a drug. An exception to this may be food allergens, which may be absorbed slowly and result in a dose-response-sensitive syndrome. Of particular concern in the perioperative setting is the presence of chlorhexidine or antibiotic-impregnated inserted devices (central venous catheters) and gelatin-based volume expanders and the potential for ongoing or prolonged anaphylaxis.

Observation After Anaphylaxis

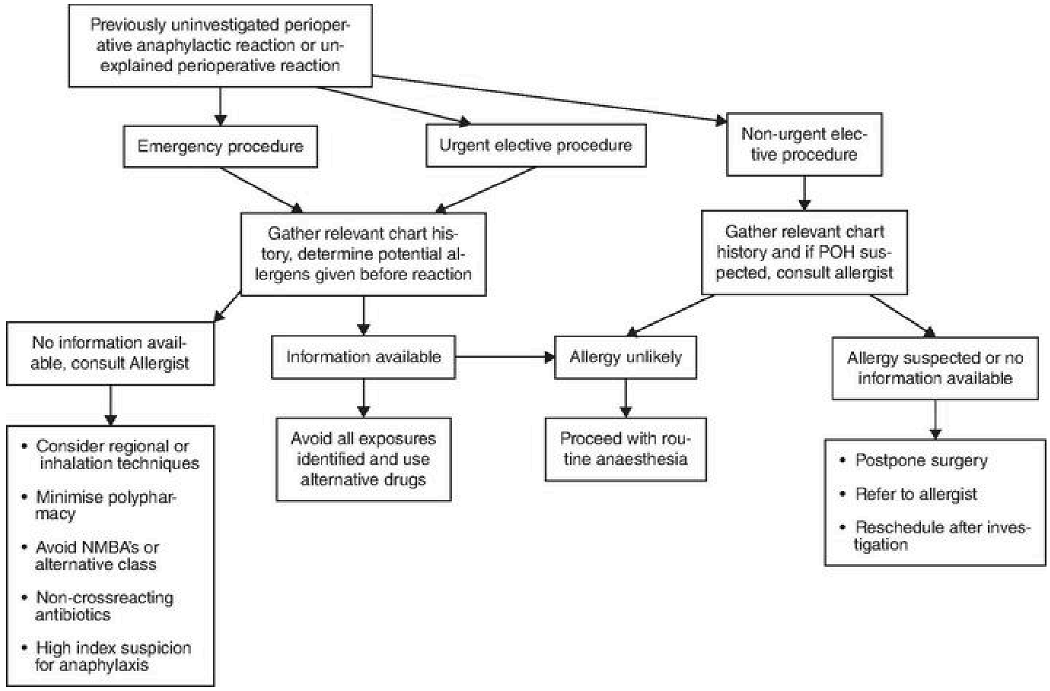
Mild cases of anaphylaxis should be observed for 4 hours, while cases that have been administered epinephrine should be observed for 6 hours after the last dose. Severe cases including those that have suffered cardiovascular collapse should be observed at least overnight. Patients with food anaphylaxis or a history of recurrent anaphylaxis are at increased risk of late complications.

Of cases admitted to intensive care for positive-pressure ventilation after intraoperative anaphylaxis, 30% are extubated within 6 hours of admission and 70% within 24 hours. [47] Extubation over an airway exchange catheter after confirmation of sufficient airway patency to allow a leak around a deflated endotracheal tube cuff appears to have a low complication rate.

Subsequent procedures during recovery from anaphylaxis

If perioperative anaphylaxis interrupts surgery, once the patient has been stabilised it may be justifiable to complete the procedure. This is feasible if the sequelae of anaphylaxis are unlikely to increase the procedure-related complications or if the procedure is unlikely to impede the ongoing management of anaphylaxis. [47]

An accurate record of potential triggers is important for planning subsequent procedures, sedation or anaesthesia. This is particularly important within the subsequent 4–6 weeks before allergological investigation can be completed (Fig. 109.1). The most common triggers are antibiotics or neuromuscular blocking agents, and therefore the greatest caution should be afforded with subsequent administration of these drugs. For non-urgent elective procedures, when an allergy is unlikely, proceed with routine anaesthesia. However, if an allergy is suspected or no information is available, postpone surgery and refer the patient to an allergist. For emergency and urgent elective procedures, gather the patient's chart history and determine potential allergens that were administered before the reaction occurred. Consider techniques such as regional or inhalation techniques, minimising polypharmacy, using non-crossreacting alternative drugs and maintaining a high index of suspicion for anaphylaxis.



Previously uninvestigated perioperative anaphylactic reaction or unexplained perioperative reaction
Emergency procedure
Urgent elective procedure
Non-urgent elective procedure
Gather relevant chart history, determine potential allergens given before reaction
Gather relevant chart history and if POH suspected, consult allergist
No information available, consult Allergist
Information available
Allergy unlikely
Allergy suspected or no information available
• Consider regional or inhalation techniques
• Minimise polypharmacy
• Avoid NMBA's or alternative class
• Non-crossreacting antibiotics
• High index suspicion for anaphylaxis
Avoid all exposures identified and use alternative drugs
Proceed with routine anaesthesia
• Postpone surgery
• Refer to allergist
• Reschedule after investigation

The flowchart outlines the management of previously uninvestigated perioperative anaphylactic or unexplained reactions. It begins with three branches, namely emergency procedure, urgent elective procedure, and non-urgent elective procedure. For emergency and urgent cases, the chart advises gathering the chart history to identify allergens. If no information is available, it leads to consulting an allergist and considering regional or inhalation techniques, minimising polypharmacy, avoiding N M B A s or using alternatives, using non-cross reacting antibiotics, and maintaining high suspicion for anaphylaxis. If information is available, the guidance is to avoid identified exposures and use alternative drugs. If an allergy is deemed unlikely, proceed with routine anaesthesia. For non-urgent procedures, the chart recommends gathering chart history and consulting an allergist if perioperative hypersensitivity is suspected. If allergy is suspected or no information is available, the path advises postponing surgery, referring to an allergist, and rescheduling after investigation.

FIG. 109.1 Approach to procedures prior to investigation of anaphylaxis. (Adapted from Garvey LH, Dewachter P, Hepner DL, et al. Management of suspected immediate perioperative allergic reactions: an international overview and consensus recommendations. *Br J Anaesth* . 2019;123(1):e50-e64. doi:10.1016/j.bja.2019.04.044.)

Follow-Up Management

After recovery from the acute event, it is essential that the patient, family and all healthcare personnel involved in the patient's care are aware of the trigger and risk of future exposure. Discharge must be with a letter with copies to all concerned detailing the event and advice should be given regarding procurement of an alert bracelet. Follow-up should be arranged with an allergy specialist for further investigations such as allergen skin tests and specific IgE tests if the trigger is unknown. Also, a risk reduction strategy should be planned including avoidance of specific triggers and training in the use of self-injectable epinephrine or desensitisation. Anaphylaxis caused by a drug or therapeutic agent should be reported to the appropriate State or National agency.

Therapeutic plasma exchange and intravenous immunoglobulin therapy

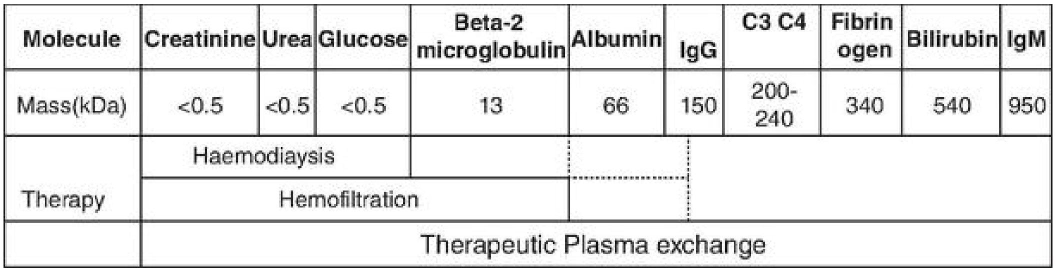
Alpesh Patel and Shailesh Bihari

Therapeutic Plasma Exchange (TPE)

Apheresis is a Greek word meaning to remove. It is used to describe a procedure to separate components of blood and selectively remove the desired component before returning blood back to the patient. Plasmapheresis is removal of plasma from the blood using a medical device and TPE means removal of plasma and exchange it with colloid (albumin and fresh frozen plasma), crystalloid or combination of them. Plasmapheresis was first described in humans in 1926 [1] and the term plasmapheresis and therapeutic plasma exchange are used interchangeably in the medical literature.

Physiological Aspects

TPE helps in removal of autoantibodies (e.g. Goodpasture syndrome, Guillain–Barré syndrome (GBS) and myasthenia gravis (MG)), immunecomplexes (e.g. systemic lupus erythematosus and acute glomerulonephritis) endogenous and exogenous metabolic products or toxin (e.g. hypertriglyceridemia, thyrotoxic crisis and fulminant hepatic failure) and also enables replenishment of deficient molecules, for example von Willebrand factor-cleaving protease (*A Disintegrin And Metalloproteinase with ThromboSpondin-1 motifs; 13th member of the family* (ADAMTS 13) molecule) in thrombotic thrombocytopenic purpura (TTP). For TPE to be effective the pathological substance implicated in the disease process should have a large molecular weight (Fig. 110.1), have low volume of distribution, slow rate of formation and long elimination half-life. This will allow rapid removal and better clinical response. However, TPE does not directly alter the rate of formation of pathological substrate hence concomitant use of immunosuppression or other specific drugs to suppress the formation of the pathological substance is necessary.



Molecule	Creatinine	Urea	Glucose	Beta-2 microglobulin	Albumin	IgG	C3 C4	Fibrin ogen	Bilirubin	IgM
Mass(kDa)	<0.5	<0.5	<0.5	13	66	150	200-240	340	540	950
Therapy	Haemodiaysis									
	Hemofiltration									
	Therapeutic Plasma exchange									

The comparative table lists various molecules by name with corresponding molecular mass in kilodaltons and applicable therapies. The molecules include creatinine, urea, and glucose, each with mass less than 0.5 kilodalton, beta 2 microglobulin with mass 13 kilodaltons, albumin at 66, I g G at 150, C 3 C 4 ranging from 200 to 240, fibrinogen at 340, bilirubin at 540, and I g M at 950. The therapy row shows haemodialysis applies to creatinine, urea, and glucose, hemofiltration applies to those three, plus beta 2 microglobulin. Albumin and I g G are partly enclosed by dotted lines, while therapeutic plasma exchange spans the entire row beneath all listed molecules.

FIG. 110.1 Removal of various molecules by haemodialysis, hemofiltration and therapeutic plasma exchange based on molecular mass (kilo Dalton, kDa). [2, 3] C, Complement; IgG, immunoglobulin G; IgM, immunoglobulin M

Technical Aspects

TPE can be performed either by centrifugation (cTPE) or membrane filtration (mTPE) (Table 110.1).

Table 110.1

Comparison between two commonly used techniques for TPE

CHARACTERISTIC	CENTRIFUGAL THERAPEUTIC PLASMA EXCHANGE (cTPE)	MEMBRANE THERAPEUTIC PLASMA EXCHANGE (mTPE)
Physical mechanism	Centrifugal force	membrane ultrafiltration
Plasma separation	Specific gravity	Molecular size
Access	Peripheral/central	Central dialysis catheter/AV fistula
Plasma extraction per pass (%)	80	30
Blood flow (mL/min)	10–150	150–300
Anticoagulation	Citrate/nil	Heparin/citrate/nil
Molecular size cut off	N/A	0.3 µm (depends on membrane)
Cytapheresis	Yes	No
Platelet contamination of plasma	More likely	No, but membrane adsorption of platelets likely
Speciality	Haematology	Renal or intensive care

Centrifugation (cTPE)

Centrifugation separates various components of blood based on their specific gravity. This is a common technique and is usually coordinated by a haematology department. It requires a relatively low blood flow of 10–150 mL/min, hence this can be performed with wide-bore peripheral venous accesses. Blood is passed through a centrifuge that separates plasma, white blood cells, platelets and red cells based on their density. The cellular component along with replacement fluid is returned to the patient. It can be performed with intermittent or continuous flow (often requiring two separate venous access). This technique is used to separate or remove plasma or various cellular components (cytapheresis) including peripheral stem cell collection. Citrate is commonly added to blood before entering centrifuge for anticoagulation. Serum calcium monitoring and replacement is advised as per local practice.

Membrane Filtration (mTPE)

Membrane-based TPE uses ultrafiltration to separate the cellular component from plasma. Blood is passed through a hollow fibre filter with larger pore size membrane (0.3–0.8 µm) with a sieving coefficient of close to one for albumin, IgG, IgM and cryoglobulin as compared to conventional hemofilter which has smaller pore size and sieving coefficient of less than 0.01 for albumin. [4,5] It can be performed on a continuous renal replacement therapy machine which has a specific TPE modality. It requires higher blood flow as compared to cTPE (around 150–250 mL/min), hence a dialysis catheter is necessary. It is simpler and easy to incorporate in intensive care units with existing continuous renal replacement therapy capability. Plasma, along with the pathological substrates, is replaced with 4% albumin, FFP, 0.9% saline or a combination to restore intravascular volume.

Both the modalities are equally safe and efficacious in removing plasma but the plasma extraction ratio per pass through the machine is higher with cTPE (80%) as compared to mTPE (30%). Higher blood flow during mTPE compensates for the lower plasma extraction ratio therefore both techniques remove equal amount of IgG and overall therapeutic effect is same. [6,7]

Prescription Aspects

Consultation: Depending on the hospital setup, the technique may vary between the centrifugal or membrane based. Depending on the diagnosis and organ involved, decision for TPE, its dose, frequency, timing and therapeutic endpoint(s) should be made with interdisciplinary consultation.

Vascular access : cTPE can be commenced through wide-bore peripheral access. For continuous cTPE two peripheral access are required. mTPE is performed through central venous access with dialysis catheter (≥12 fr) in an internal jugular, femoral or subclavian vein. If citrate is used for anticoagulation then a triple lumen catheter could be considered to facilitate calcium infusion. Catheter care in between the therapy should be as per local infection control policy. Maximum blood flow in mTPE will be guided by filter used and the patient's hemodynamic tolerance. However, increasing blood flow to more than 250 mL/min increases the risk of circuit loss (high transmembrane pressure) and hypocalcaemia.

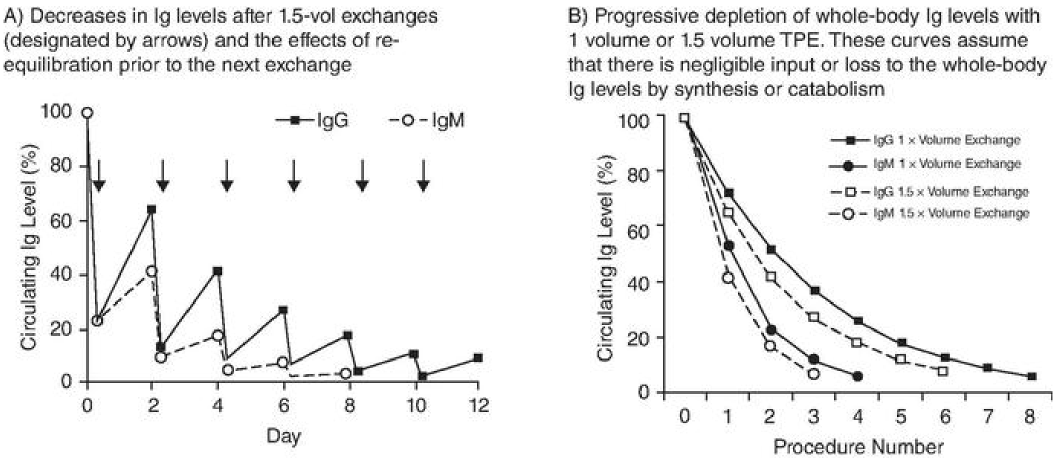
Dose: Dose remains the same for cTPE and mTPE. TPE only eliminates a fraction of the substance dissolved in plasma, hence the efficiency of substance removed with TPE will depend on the volume of distribution of the substance and the amount of plasma volume replaced during TPE. Plasma volume is estimated using formula [8] :

$$\text{Estimated plasma volume (EPV)} = \\ \left[0.065 \times \text{weight}(\text{kg})\right] \times \left[1 - \text{Haematocrit}\right]$$

The dose for TPE is 1 to 1.5 times the estimated plasma volume (EPV).

Ideal body weight is used for the calculation of plasma volume hence it may not be very accurate in patients with extremes of BMI. [9]

Rationale for dose and timing: TPE reliably reduces the level of desired high molecular substance to a level predicted by one compartment model based on their volume of distribution. In a single TPE procedure, the amount of plasma removed varies according to the volumes of plasma exchanged following an exponential curve (Fig. 110.2). Thus increasing the volume of plasma exchanged beyond 1.5 times the EPV does not add much benefit but potentially can increase the risk of side effects. The rate of removal also depends on the intravascular distribution of the target molecule. For example IgM antibodies are predominantly intravascular as compared to IgG antibodies hence a larger amount of IgM antibodies can be removed per plasma volume exchange compared to IgG antibodies. To allow for the redistribution of the target molecule from interstitial to intravascular compartment TPE is often performed every alternate day unless the rate of production or antibodies is very high. [10], [11]



A) Decreases in Ig levels after 1.5-vol exchanges (designated by arrows) and the effects of re-equilibration prior to the next exchange

B) Progressive depletion of whole-body Ig levels with 1 volume or 1.5 volume TPE. These curves assume that there is negligible input or loss to the whole-body Ig levels by synthesis or catabolism

The two line graphs show I g G and I g M levels over days of treatment and the number of procedures during volume exchange therapy. The left graph presents circulating I g G and I g M levels as a percentage over time from day 0 to day 12. Arrows mark treatment days at 0, 2, 4, 6, 8, and 10. Both lines exhibit drops after each treatment, followed by partial recovery. The right graph shows changes in circulating I g G and I g M levels relative to procedure number from 0 to 8. Four curves are included, I g G and I g M with 1 times volume exchange (solid square and solid circle), and I g G and I g M with 1.5 times volume exchange (open square and open circle).

FIG. 110.2 Hypothetical depletion of whole body immunoglobulin (Ig) levels by therapeutic plasma exchange (TPE), using a continuous flow method, performed every 2 days, as predicted by a 1-compartment model and using known intravascular/extravascular distribution ratios for IgM and IgG. [11]

Anticoagulation: The available options are the use of regional citrate, prostacyclin, systemic heparin or no anticoagulation. Citrate (2% acid citrate dextrose) is most commonly used for anticoagulation during cTPE due to its familiarity with the blood bank. Most of the citrate is removed with plasma during centrifuge. mTPE can be performed with or without anticoagulation. [2] Regional citrate anticoagulation (RCA) is often used and the citrate (2% acid citrate dextrose) dose is titrated to the blood flow with an aim to achieve post-filter ionised calcium level of <0.35 mmol/L. [12]

Drop in serum ionised calcium concentration happens early, within 15 minutes of initiation of TPE, hence its level is frequently monitored and kept in normal range using calcium gluconate or calcium chloride infusion as per local protocol. Due to significant loss of citrate-bound calcium via TPE filter, often a higher dose of calcium replacement is required as compared to continuous renal replacement therapy (CRRT) with RCA. Heparin is commonly used by nephrologists due to their familiarity with it. However, as heparin and antithrombin III are cleared by plasma filter, often a higher dose is required as compared to that used in the usual CRRT protocol.

Replacement fluids: Most TPE can be performed with 4% or 5% albumin as replacement fluid. In thrombotic thrombocytopenic purpura, FFP or cryosupernatant, plasma is used to replenish the deficient ADAMTS 13 enzyme. If bleeding risk is high or the patient is due for a surgical procedure post-TPE, FFP or often a combination of albumin and FFP can be used. It is advisable to administer FFP during the latter part of TPE to reduce the loss of the administered coagulation factor. If a crystalloid such as 0.9% saline is used as a replacement, then a higher replacement volume (1.25 times plasma removed) will be required to avoid hypotension due to extravascular fluid shifts.

Indications for TPE

The apheresis application committee of the American Society for Apheresis (AFSA) publishes evidence-based practice guidelines for therapeutic apheresis indications It serves as a key resource that guides the utilisation of TPE in the treatment of diseases. [13] Table 110.2 outlines common indications for TPE in ICU. [14]

Table 110.2

Common disorders in ICU in which TPE is indicated along with the evidence grade and category based on AFSA guidelines [13]

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
Acute inflammatory demyelinating polyradiculoneuropathy (GBS)	I/1A	IVIg and TPE are equally effective. [15] No added advantage of combined therapy 1–1.5 × EPV 5–6 times, alternate days or daily. Can be repeated for relapse. RF: albumin or albumin + plasma. [16]
Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)	I/1B	TPE and IVIg are equally effective in neurological improvement. [17, 18] 1–1.5 × EPV 2–3 times/week until neurological improvement. RF: albumin.
Myasthenia gravis	I/1B	Indications are myasthenic crisis and stabilising the clinical state prior to thymectomy. TPE and IVIG are equally effective. [19] TPE should be initiated early [20] and concomitant

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		immunosuppression must be initiated. 1–1.5 × EPV daily or alternate day titrated to clinical response. RF: albumin.
N-methyl d-aspartate receptor (NMDAR) antibody encephalitis	I/1C	More common in children and young females. Presents with neuropsychiatric symptoms. Diagnosis: NMDAR antibodies in CSF. High-dose pulse corticosteroids followed by IVIG, or TPE/IA, and a search for potential underlying tumour (teratoma). 1–1.5 × EPV TPE (10–12 treatments) and IA are equally effective. [21]
Familial hypercholesterolemia	II/1B	Adsorption-based lipid apheresis is preferred. Target: Inter-apheresis LDL-C level ≤120 mg/dL.
Thyroid storm	II/2C	Drugs blocking thyroid hormone synthesis (propylthiouracil [PTU] and release (iodine, lithium), blocking T4

DISEASE	**AFSA CATEGORY AND GRADE** [a]	**TECHNICAL DETAILS**
		to T3 conversion (glucocorticoids), inhibiting the enterohepatic circulation of thyroid hormone (cholestyramine), controlling the adrenergic effects of the thyroid hormones (ß-blockers) are first line. TPE is indicated as an adjunct if refractory to the above measures or persistent cerebral symptoms.
Focal segmental glomerulosclerosis	I/1B	For recurrence in transplanted Kidney (I/1B) or steroid-resistant in the native kidney (III/2C).
Anti-glomerular basement membrane (anti-GBM) disease (Goodpasture syndrome)	Diffuse alveolar haemorrhage (DAH): I/1C Dialysis dependence: III/2B	Presents with prodromal symptoms with haematuria and/or haemoptysis due to small vessel vasculitis from deposition of anti-GBM autoantibodies. Histologically: RPGN and DAH. Prompt initiation of TPE along with

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		immunosuppression significantly improves renal outcome and DAH.[22,23] 1–1.5 × EPV daily or alternate days till improvement in renal or pulmonary injury. RF: albumin/albumin + FFP in DAH.
Renal transplantation ABO incompatible	I/1B	Used along with IVIg and rituximab in patient on transplant list with elevated HLA antibody titre from previous transfusions, pregnancy for desensitisation. Similar therapy is also used for antibody-mediated rejection (AMR) post-transplant. 1–1.5 × EPV with albumin or FFP as replacement. 5–6 treatments guided by risk for AMR and DSA titre.
Antineutrophil cytoplasmic antibody (ANCA) associated vasculitis	I/1A	Variable practice in patients with acute renal failure or pulmonary haemorrhage along with steroid pulse and immunosuppressive therapies. Recent review

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		does not support routine use. [24]
Hyper viscosity (HVS) in monoclonal gammopathies [25]	I/1B: Symptomatic I/1C: Prophylaxis for rituximab	Commonly associated with Waldenström's macroglobulinemia (IgM) or, less frequently, with multiple myeloma (IgA or IgG3). HVS often have a plasma viscosity of >4 centipoise (normal 1.4–1.8 centipoise). 1–1.5 × EPV daily or alternate day to reduce antibody (IgG, IgM or IgA). Prophylactic TPE is performed prior to rituximab initiation to reduce IgM level <4 g/dL.
Cryoglobulinaemia	II/2A	Immunosuppression is the mainstay therapy. TPE is indicated as an adjunct to rapidly remove cryoglobulins causing severe end-organ involvement (RPGN, intestinal ischaemia, neuropathy). [26]

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		Preferably keep replacement fluid, room and tubing warm during TPE to prevent intravascular precipitation of cryoglobulins. Clinical response and cryocrit level are used to guide response to TPE. [27] 1–1.5 × EPV alternate days. RF: albumin.
Wilson's disease fulminant	I/1C	TPE is utilised as bridge to liver transplant. Reduces copper level rapidly.
Acute liver failure	I/1A TPE-(high volume)	8–12 L exchange daily for 3 days, FFP as RF improves transplant-free survival in ALF. [28]
	III/2B for TPE	1–1.5 × EPV reduces ammonia, bilirubin and other biochemical markers. Rapidly correct coagulopathy. No mortality benefit [29] especially if used in conjunction with high-volume hemofiltration.
Severe hyper triglyceridemic	III/1C	Indicated along with lipid-lowering agents

DISEASE	**AFSA CATEGORY AND GRADE** [a]	**TECHNICAL DETAILS**
pancreatitis (triglyceride level >1000 mg/dL or 11.3 mmol/L)		(statins, fibrates, insulin infusion and heparin). Due to higher molecular size filter clogging is common during mTPE 1–1.5 EPV aim to reduce TG by 50%. RF: albumin/plasma (to replace lipoprotein lipase level).
Dilated cardiomyopathy idiopathic	III/2C for TPE II/ 1B for IA	Immune adsorption (IA) is more effective than TPE, especially when positive autoantibodies towards various myocardial antigens on myocardial biopsy. Often followed by IVIG infusion post-last IA/TPE. Used along with standard medical management. [21]
Thrombotic thrombocytopenic purpura (TTP)	I/1A	Urgent indication. Rest as described in the text.
Thrombotic microangiopathy (TMA) complement-mediated (atypical HUS)	I/2C (Factor H autoantibody)	Eculizumab is first-line therapy. TPE indicated in undifferentiated TMA awaiting diagnosis or if

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		eculizumab is not available. Dose: 1–1.5 × EPV daily, RF: FFP or FFP + albumin.
Drug-associated thrombotic microangiopathy	I/2B (Ticlopidine)	Drugs associated with TMA include: clopidogrel, calcineurin inhibitors (CNIs), oestrogen/progesterone, gemcitabine, interferon, mitomycin, quinine, and ticlopidine. Ticlopidine-induced TMA presents within two weeks of initiation and is associated with low ADAMTS13 levels (<10%) TPE initiated awaiting results.
Catastrophic antiphospholipid syndrome (CAPS)	I/2C	Therapeutic anticoagulation, systemic steroid and TPE/IVIG along with treatment of precipitating factor are indicated. 1 × 1.5 × EPV daily or alternate days. RF: albumin plus FFP to replenish antithrombin level for effective

DISEASE	AFSA CATEGORY AND GRADE [a]	TECHNICAL DETAILS
		heparin anticoagulation.
Sepsis with multi-organ failure	III/2B	As an adjunct to standard care shown to reduce organ dysfunction score in small RCTs with variable effect on mortality. Other modalities like high-volume hemofiltration, and hemadsorption filters are increasingly used. 1–1.5 × EPV started early in the course. RF: FFP + albumin.

[a] Category I: Disorders for which apheresis is accepted as first-line therapy, II: apheresis is accepted as second-line therapy, III: role of apheresis not established and decision should be individualised, IV: evidence suggesting ineffectiveness or harm with apheresis.

Grade 1A: Strong recommendation, high-quality evidence, 1B: strong recommendation, moderate quality evidence, 1C: strong recommendation, low-quality evidence, 2A: weak recommendation, high-quality evidence, 2B: weak recommendation moderate quality evidence, 2C: weak recommendation, low-quality evidence (other alternative reasonable).

Common Indications for TPE in ICU

Thrombotic thrombocytopenic purpura (TTP): TTP is a form of thrombotic microangiopathy (TMA), characterised typically by fever, microangiopathic haemolytic anaemia (increased schistocytes on peripheral blood smear, raised lactate dehydrogenase (LDH)), profound peripheral thrombocytopenia (platelet count $<30\times10^{9}$/L), neurological and renal impairment. It can be congenital or acquired and is associated with severe deficiency of the (<10%) ADAMTS13 due to autoantibodies against ADAMTS13 (autoimmune TTP).

TTP is universally fatal if not treated urgently. Due to the long turnaround time for ADAMTS 13 levels, TPE should be urgently started if TTP is suspected or not ruled out in a patient with TMA. A seven-component clinical predictor tool (platelet count $<30\times10^{9}$, haemolysis on blood film or low haptoglobin, no active or recently treated cancer, no history of solid organ or stem cell transplant, MCV <90 fL, INR <1.5, creatinine <2 mg/dL), termed PLASMIC score is shown to be reliable in assessing the pretest probability of severe ADAMTS 13 deficiency. Each component of the PLASMIC score is worth one point and a score of more than 5 suggests high risk and consideration for urgent TPE.[30] TPE allows removal of ADAMTS 13 antibodies and fresh frozen plasma is used for replacement which replete ADAMTS 13 levels. Daily or twice daily plasma exchange with 1.5 times EPV with FFP is indicated. Cryosupernatant plasma, which is deficient in high molecular weight VWF multimers, can be used in place of FFP, however, this has a similar patient-related outcome.[31,32] Platelet transfusion should be avoided unless the patient has severe haemorrhage. TPE is continued till the platelet count is above 150×10^{9}/L and the LDH level is within reference range for 2–3 days. LDH and bilirubin are removed during TPE, hence sustained reduction in levels post cessation of TPE is necessary to guide response. Persistence of red cell fragments on peripheral smear, in the absence of other clinical and biochemical features does not preclude discontinuation of TPE. Many centres taper TPE gradually over a few days by reducing the dose to 1 × EPV or increasing the interval between TPE to avoid relapse. Urgent TPE initiation has reduced the mortality of TTP by 85%. If TPE is not available then plasma infusion should be initiated while awaiting transfer to a centre with TPE service.

It is important to differentiate TTP from haemolytic uraemic syndrome (HUS) (Shiga-toxin-mediated or atypical HUS (aHUS)), as there is clinical overlap between them but treatment options vary with the diagnosis. Shiga-toxin HUS is often preceded by bloody diarrhoea caused by Shiga-toxin-producing bacteria (predominantly *E. coli* O157:H7) and stool culture and/or PCR for Shiga-toxin will be positive. Management includes hydration and supportive care, and TPE is not indicated.

Diagnosis of aHUS relies on the absence of criteria for Shiga-toxin HUS, that is, negative stool culture and PCR for Shiga-toxin, ADAMTS 13 activity >10% in the presence of TMA and acute kidney injury. Eculizumab, a humanised anti-C5 monoclonal antibody, blocks activation of the terminal complement cascade, and is considered as first-line therapy for aHUS. TPE removes the autoantibody or mutated circulating complement regulators while replacing absent or defective complement regulators and should be initiated while other forms of TMA are ruled out or if eculizumab is not available (Category III, Grade 2C) especially if Factor H autoantibodies (Category 1, GRADE 2C) are present.

Myasthenia gravis (MG): Indications for TPE are myasthenic crisis with bulbar and severe skeletal muscle weakness, stabilising the clinical state pre-thymectomy and drug-refractory disease. High-dose IVIg and TPE are equally effective, and the decision is guided by local practice. [19] Concomitant immunosuppression must be initiated or modified for sustained control of MG activity.

Inflammatory demyelinating neuropathies and GBS : The most common aetiology is autoimmune antibody-mediated destruction of the myelin sheath of the peripheral nerve often preceded by viral or bacterial infection or other immune stimulation like vaccination. Other variants of classic GBS are caused by immune attacks against axons. TPE initiated early, preferably within 7 days of disease onset, is associated with accelerated neurological recovery and improved ventilatory weaning. IVIG is equally effective as TPE but combining both therapies has shown no additional benefit. [15], [16]

Fulminant hepatic failure : Rationale for TPE in fulminant hepatic failure includes removal of albumin-bound toxins such as ammonia, replacement of deficient coagulation products and reduction in proinflammatory response. Standard TPE (1 to 1.5 times EPV) is associated with a reduction in ammonia and other biochemical parameters, with a variable effect on vasopressor requirement in the reported case series. High-volume TPE (TPE-HV), defined as plasma replacement at 15% of ideal body weight or 8 to 12 L per session, performed for three consecutive days has been shown to significantly improve biochemical, hemodynamic parameters and transplant-free survival in patient not listed for liver transplantation.[28] However, high-volume haemofiltration, a common practice in these patients was not mandatory in the standard medical management group. Hence TPE-HV utilisation in fulminant hepatic failure varies.

Consideration for TPE during pregnancy: TPE can be safely delivered during pregnancy. Plasma volume is increased during the second trimester of pregnancy by approximately 50% and this should be taken into consideration when calculating EPV for TPE. It is assumed that an increase in maternal weight will reflect the increase in volume and hence either actual weight or increasing volume exchange can be considered. Close hemodynamic monitoring during TPE is recommended as there is a high risk of hypotension secondary to impaired venous return from the gravid uterus and this can lead to impaired placental blood flow. However, available data suggest foetal circulation is uncompromised during TPE and routine foetal monitoring during TPE is not necessary and should be guided by an interdisciplinary approach that involves an obstetric team. If TPE is performed in the third trimester prior to delivery, FFP should be added to replacement volume and fibrinogen level monitored post-TPE to reduce the risk of postpartum haemorrhage. Due to the increased risk of infection during pregnancy cTPE with peripheral access is preferred over large bore central access if possible. Common indications for TPE during pregnancy are similar to the general population as per American Society for Apheresis guidelines. Additional obstetric-related indications include HELLP syndrome (haemolysis, elevated liver enzyme and low platelet count). Delivery of the baby is the definitive treatment for HELLP and should not be delayed for TPE. If thrombotic microangiopathy persists post-partum then TPE can be performed (Category III/2C).[33]

Complications

TPE is a relatively safe procedure with more than 90% of procedures having no reported patient complications. Circuit-related complications such as elevated transmembrane pressure (TMP), and circuit clotting are common with mTPE.[34],[35] Table 110.3 highlights the commonly reported complications.

Table 110.3

Complications of TPE

Access related
Thrombosis
Central line-related bloodstream infection
Pneumothorax
Bleeding
Circuit complications
Clotting
High transmembrane pressure
Air in circuit
Filter fracture
Replacement fluid and anticoagulation-related complications
Hypocalcaemia
Transfusion reaction: urticaria, rash, anaphylaxis
Depletion coagulopathy
Immunoglobulin depletion
Viral transmission
Hypotension
Citrate accumulation/toxicity

Access-related complications : This can be minimised by using standard aseptic precautions, ultrasound-guided insertion of access catheters and use of heparin or citrate-based locks in between the therapy. Transition to a long-term dialysis catheter for patients requiring long-term TPE is preferable.

Hypotension: This is rare and mostly reported when crystalloid is used as the replacement fluid rather than albumin or FFP. [34] Hypotension can be minimised by adding colloid (4%–5% albumin or FFP) to the replacement volume. Profound hypotension can be a sign of a transfusion reaction.

Electrolyte disturbances: Hypocalcaemia is common with citrate anticoagulation or when FFP is used as a replacement fluid. [35] This is mostly asymptomatic but can manifest as perioral tingling, hypocalcaemic tetany, rarely prolonged QTc and cardiac arrhythmias. It can be avoided by frequent monitoring of ionised calcium during and at cessation of therapy and using calcium replacement. Hypomagnesaemia and hypokalaemia may occur due to citrate binding and elimination via filter.

Depletion of coagulation factors: Depletion of coagulation factors due to their elimination can increase the risk of bleeding. Depletion in coagulation factors will depend on volume, frequency, type of replacement fluid and baseline levels. Using albumin or saline as the replacement fluid, coagulation factors tend to be reduced by 20%–25% during an exchange. These levels mostly return to baseline within 24 hours and FFP is not routinely indicated as a replacement fluid unless there is a high risk of bleeding. As fibrinogen has a long synthetic half-life (3 days) a pre-TPE session fibrinogen level can be used as a marker for determining FFP in replacement volume. On average, 20%–25% of replacement volume as FFP administered during the latter part of TPE will maintain adequate haemostasis post procedure in patients with an increased bleeding risk. There is a drop in platelet count of approximately 10% to 20% post-TPE, either due to membrane adsorption during mTPE or inadequate separation during cTPE. This is generally well tolerated and platelet transfusion is not routinely required.

Transfusion-related complications: If blood products as part of TPE, the patient should be closely monitored for transfusion reactions during and after the procedure. It can manifest as fever, rash, urticaria, hypotension or rarely anaphylactic shock. While not routine, some centres administer prophylactic antihistamine and steroid. Rare, atypical anaphylactoid reactions in patients on angiotensin-converting enzyme inhibitors have been reported, likely due to kinin release. It is advised to withhold angiotensin-converting enzyme inhibitors for 24 hours before the therapy, if safe. If multiple TPE sessions are performed over a short period of time, it can lead to immunoglobulin deficiency and increase susceptibility to infection. Depending on the clinical situation IVIg infusion can be administered post completion of TPE therapy in immunocompromised patients.

Drug elimination during TPE: TPE removes protein-bound drugs, this may have serious implications for the patient if a sustained concentration of a drug is needed (e.g. antimicrobials with concentration-dependent killing, antiepileptics and anticoagulants). The pharmacokinetic properties of drugs which favour elimination are low volume of distribution (<0.2–0.3 L/kg), high protein binding (>80%) and long half-life (>2 hours). Procedure-related factors which can promote drug elimination include dose (amount of plasma volume removed), frequency, duration, timing of TPE and the type of replacement fluid used. If TPE is performed soon after a drug is administered then a greater concentration of drug will be eliminated during its distribution phase. Generally, drugs with low volume of distribution and high protein binding should be administered post- TPE. Some commonly used drugs in critically ill patients which can be readily removed during TPE are heparin, enoxaparin, apixaban, warfarin and ceftriaxone. When possible, use therapeutic drug monitoring and monitor the clinical status of the patient closely. [36-38]

Immunoadsorption systems (IA): They remove immunoglobulins by binding them to ligands (e.g. staphylococcal or recombinant protein A, sheep polyclonal anti-human antibodies, tryptophan, synthetic oligopeptides and monoclonal camel antibody fragments) on the columns. Most IA columns non-specifically adsorb immunoglobulin, but specific antibody columns exist. The major advantage of this procedure as compared to TPE is that no substitution of plasma is required. IA can be as effective as TPE for many of the above indications but the comparative data is currently lacking.

Intravenous Immunoglobulin (IVIg)

IVIg preparations are composed of a broad range of immune antibodies directed against pathogens and foreign antigens, natural autoantibodies and anti-idiotypic antibodies. They are derived from human plasma obtained from large pools of healthy blood donors and are used as substitution therapy in patients with antibody deficiency or as immunomodulatory and anti-inflammatory therapy in various autoimmune, and infectious disorders.

IVIg is produced from the fractionation of proteins in pooled human plasma using the Cohn–Oncley process (a process by which the major proteins within the plasma are selectively precipitated using variations in the concentration of ethanol, polyethylene glycol, short fatty acid, temperature and pH) and or a chromatographic process (separation of plasma proteins based on their size and charge rather than their solubility). The composition of IVIg and production is strictly regulated by national drug authorities. WHO guidelines stipulate that IVIg preparations are obtained from a plasma pool of more than 1000 healthy individuals, who are regular blood donors. They must not transmit infectious agents, they must have a defined concentration of immunoglobulin G (IgG), they must contain at least two antibody specificities (antiviral and antibacterial), for which there is an international standard or a reference preparation, and identified in a concentration of at least three times higher than that of the original plasma pool. Finally, preparations of immunoglobulin can not exhibit thrombogenic activity (procoagulant) and IgG contained in the preparations must be intact and have a functional crystallisable constant fragment (Fc). Concentration of various IgG subclasses is identical to normal human plasma. Regulatory oversight also ensures that there is a significantly low risk of viral or prion transmission. [39] Although all commercially available preparations of IVIg have similar clinical efficacy, they vary slightly in their biochemical and biological properties depending on their donor pool and preparation methods. [40]

Mechanism of Action of Intravenous Immunoglobulin

Mechanism of action of IVIg at replacement dose: Approximately 90% of immunoglobulin in IVIg are IgG. Low-dose IVIg infusion replaces the IgG levels and confers passive immunity against various bacterial and viral antigens. [41] IgG is composed of two variable regions responsible for fragment antigen-binding (Fab) and a constant region of crystallisable fragment (Fc). Fab portion binds with foreign antigen or toxin and neutralises it or facilitates opsonisation. This is the primary mechanism of action when low-dose IVIg is infused as a replacement therapy for primary or secondary humoral immunodeficiency arising from reduced or absent production or defective function leading to recurrent infections. The Fc fragment binds with the complement and also induces maturation of dendritic cells leading to stimulation of T helper cells. [42] Due to this, the immunological benefit outlasts the half-life of the administered immunoglobulin.

Mechanism of action of high-dose IVIg: High-dose IVIg is used in various autoimmune and inflammatory disorders. These inflammatory disorders are characterised by micro thrombosis, compliment-mediated cytotoxicity, uncontrolled neutrophil activation, cellular lysis (immune thrombocytopaenic purpura (ITP)), blockade of neuronal transmission (MG) or stimulation of hormonal receptor (Graves' disease). The immunomodulatory effect of IVIg is mediated by one or more of the following actions. [43]

1. Anti-idiotypic antibodies in IVIg bind and neutralise circulating autoantibodies to molecules such as factor VIII, acetylcholine receptor, cardiolipin and ganglioside.
2. The Fc portion of IVIg binds with complement protein and steers it away from autoantibodies resulting in the neutralisation of chemicals responsible for compliment-mediated inflammation.
3. Saturation of neonatal Fc receptors on immune cells by antibodies in IVIg preparation attenuates immune complex-mediated inflammatory and autoimmune response (leading to an increase in platelet count in ITP).
4. It alters the cellular immune response by inhibiting the activation of monocyte macrophages and the maturation of dendritic cells. It induces the expansion of the regulatory T cell population and suppresses B lymphocytes and neutralises the cytokines released from them, thereby promoting immunosuppression. [44-46]
5. Inhibits apoptosis and blocks endothelial cell proliferation in inflammatory vasculitis. [47], [48]

Hyperimmune immunoglobulin: These are polyclonal antibodies derived from convalescent plasma with a high titre of antibodies against a particular antigens. It provides immediate passive immunity against particular antigen. It can be used as pre-(CMV) or post-exposure prophylaxis (hepatitis B, rabies, varicella, RSV and tetanus) in susceptible individuals and as a treatment for anthrax and infant botulism. Anti-Rho (D) is used in pregnant females to prevent isoimmunisation and treatment of idiopathic thrombocytopaenic purpura.

Pharmacokinetics: Commercially available IVIg preparations have a similar half-life to endogenous IgG (range between 21 and 32 days), hence they are prescribed monthly for replacement. Half-life can be shortened in individuals with hypoalbuminemia such as seen in IgG paraproteinemia, nephrotic syndrome and protein-losing enteropathy, due to increased catabolism of unbound IgG.

Dose: The recommended initial dose for replacement therapy is 400–600 mg/kg every 3–4 weeks. A trough IgG level of more than 700 mg/dL is associated with reduced infection and improved clinical outcomes.

High-dose IVIg : 2 g/kg as a single dose or given over 5 days is the commonly prescribed dose.

Indications

Due to the diverse mechanisms of action of IVIg it has been used in a broad range of diseases. As it has limited availability and can lead to adverse effects, various national drug and blood regulatory authorities and societies have developed evidence-based guidelines for IVIg use.

Replacement therapy for primary and secondary immunodeficiency (Table 110.4): IVIg replacement therapy can be life-saving for patients with severe primary immunodeficiency that directly affects B-cell function and antibody production. In hypogammaglobulinaemia with significant inability to respond with IgG antibody on antigen challenge (e.g. common variable immunodeficiency), IVIg replacement reduces lung infection.[41]

Table 110.4

CLL , chronic lymphocytic leukaemia; *PI* , primary immunodeficiency.

Derived from the work group report of the American Academy of Allergy, Asthma & Immunology.[49]

High-dose IVIg: IVIg is used for various haematologic autoimmune diseases, rheumatic diseases, and organ-specific autoimmune diseases (Table 110.5). Newer biological agents and immunomodulation therapies have reduced the role of IVIg as first-line therapy apart from GBS, idiopathic thrombocytopenic purpura (ITP), chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), Graves ophthalmopathy and multifocal motor neuropathy.

Derived from the work group report of the American Academy of Allergy, Asthma & Immunology. [49]

GBS: High-dose IVIg started within 2 weeks of onset and TPE are equally effective in improving neurologic outcomes. [50] Choice will depend on individual circumstances.

Sepsis, septic shock and toxic shock syndrome: There is variable evidence for the use of IVIg as an adjunct in neonatal sepsis along with conventional care, with some earlier meta-analyses suggesting a six-fold decrease in mortality while recent large-scale studies showing no mortality difference. [51-53] This could be due to inconsistencies in the definition of sepsis and variability in the conventional care received.

Toxic shock syndrome is a severe complication of invasive group A streptococcus (GAS, *Streptococcus pyogenes*) infection associated commonly with necrotising soft tissue infection, peri partum genital/endometrial infection and bacteraemia. Around 60% of cases have positive blood cultures for GAS. The remaining cases have GAS identified from non-sterile or sterile site cultures. It is characterised by symptoms of underlying invasive infection and rapid onset (within hours) of often vasopressor refractory septic shock and multiple organ failure. It is caused by hyperstimulation of inflammatory response mediated by streptococcal superantigens (endotoxin). IVIg as adjunctive therapy at a dose of 1 g/kg on day one and 0.5 g/kg on days 2 and 3 is recommended along with IV antibiotics (beta-lactam and clindamycin), source control and supportive management for septic shock and multi-organ failure. [54]

COVID-19: Rationale for TPE and IVIg use in severe COVID-19 includes immunomodulation by removal or reduction in inflammatory cytokine levels and reduce hypercoagulopathy by replacing deficient metalloproteinases, removing procoagulant substances and preventing immune-mediated microthrombosis. They are used in patients with severe COVID-19 with variable results. Most of the reported trials are from pre-COVID vaccination era and other immunomodulatory drugs like steroids and tocilizumab are shown to be more effective. Available evidence does not support their use outside of clinical trials. [55], [56]

Vaccine-induced immune thrombotic thrombocytopenia (VITT) [57] : It is an extremely rare syndrome reported in individuals who received certain adenoviral-vectored COVID-19 vaccines. Proposed mechanism for VITT is platelet activation by antibodies that recognise platelet factor 4 (PF4) bound to platelets leading to thrombosis. The diagnosis of VITT is considered confirmed by a positive PF4 enzyme-linked immunosorbent assay (ELISA) or functional assays such as the serotonin release assay (SRA), in the appropriate clinical context of thrombosis (within 5–30 days post COVID-19 vaccine exposure) and/or thrombocytopenia (including lack of recent heparin exposure to explain the positive ELISA). Treatment should be initiated if there is a high clinical likelihood of VITT awaiting confirmatory test results. High-dose IVIg (1 g/kg daily for 2 days) is recommended (low-quality evidence and expert recommendation). [58] TPE (1–1.5 times EPV exchange for 5 days or until platelet count recovery) is proposed if there is persistent thrombocytopenia and evidence of ongoing thrombosis or cerebral sinus thrombosis, post initiation of IVIg and non-heparin based anticoagulation.

Adverse Reactions

Commercially available IVIg preparations are well tolerated. Factors associated with high adverse events include higher concentration, higher rate, lyophilised products and IgA deficiency in recipients. Mild adverse reactions are common (5%–15% of infusions) and include headache, flushing, chills, abdomen or back pain, myalgia and hypotension. This adverse reaction can be treated by temporarily ceasing (for 15–30 min) and then restarting the infusion at a lower rate and administering premedication (antihistamines and steroids) one hour before commencing the infusion.

Anaphylactic reaction is rare but can occur in IgA-deficient patients. It can be avoided by using IgA-depleted preparation or using subcutaneous immunoglobulin preparation.

Other uncommon but significant complications associated with high-dose IVIg include thromboembolic events, renal toxicity, haemolysis and neurodegeneration. Risk factors for thromboembolic events (cerebral ischaemia, stroke, myocardial infarction, deep vein thrombosis and pulmonary embolism) include pre-existing cardiovascular disease, diabetes mellitus, dehydration, age >65 years, sepsis, paraproteinemia, increased blood viscosity, hypercholesterolemia and hypertension. It is likely related to the hyperosmolality of the preparation and the presence of procoagulant factors (Factor XIa) in the preparation. Renal toxicity is associated with sucrose-containing products (osmotic nephrosis). Newer products have substituted sucrose with amino acid as a stabiliser and eliminated factor XIa during the manufacturing process and are considered safe. Mild self-limiting haemolysis due to residual anti-A and anti-B antibodies may regularly occur but haemolytic anaemia is rare.

Modern sterilisation processes used during the manufacturing of IVIg have virtually eliminated the risk of viral and bacterial transmission. Infusion site-related infectious and thrombotic complications require consideration and monitoring when indwelling venous catheters are used for the long term. Due to the above risks, IVIg infusion should be monitored closely.

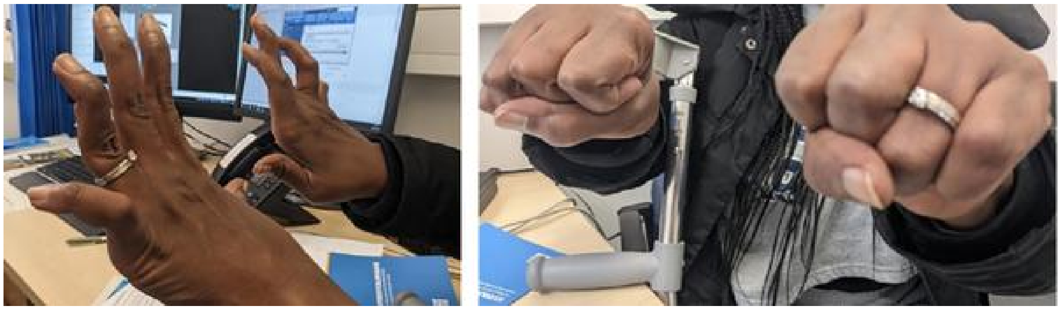
Systemic Lupus Erythematosus

Background

Systemic lupus erythematosus (synonymous with lupus, SLE) is a classical autoimmune condition affecting multiple organ systems and with great variation in presentation, severity and outcome. [1] SLE manifestations are due to the effects of autoantibodies, immune complex formation or else through non-antibody mediated effects. SLE predominantly affects young non-Caucasian females and has a high prevalence in inner city populations in developed countries. In London, SLE has a high prevalence exceeding that of multiple sclerosis or inflammatory bowel disease, presenting to rheumatology clinics with musculoskeletal symptoms, dermatologists, renal physicians, or via acute medical admission with systemic illness or sepsis. [2-4] Age at onset varies according to racial groups, typically presenting at 18–25 years in Bengali patients, 20–35 years in Black patients and later in mid-life in Caucasian patients.

There are myriad clinical manifestations and SLE is considered a great mimic of other inflammatory syndromes. Clues to lupus being the underlying disorder include the typical pattern on blood testing of high erythrocyte sedimentation rate (ESR) with normal C-reactive protein levels, haematologic features such as reduced platelet count and leukopenia. Common physical signs would include small joint synovitis, patchy hair loss and malar or limb-based subacute cutaneous rash during admission with active disease.

In general, the majority of patients will experience musculoskeletal symptoms such as arthralgia or myalgia during active disease. [5] The arthropathy is non-erosive and can vary from simple arthralgia without overt clinical signs or else a symmetrical small joint inflammatory arthropathy leading to soft tissue damage and eventual Jaccoud's pattern arthritis (deforming but non-erosive with swan-neck and Z deformity of the thumb) (Fig. 111.1).



The set of three photographs shows a clinical hand assessment. The first visual shows a person holding both hands in front of a computer monitor with fingers extended and slightly spread, with bent joints. The second and third visuals show the same individual with both hands clenched into fists, held horizontally and close to the camera.

FIG. 111.1 Deforming but non-erosive arthropathy (Jaccoud's) in SLE . Swan-neck deformities fully reduce finger flexion, unlike rheumatoid where erosive changes lead to loss of full finger flexion.

Dermatologic manifestations are multiple but include the classic malar rash, which is linked to active systemic disease; limb-based subacute cutaneous lupus with macular erythematous lesions, seen in association with anti-ro antibodies and exacerbated by the use of omeprazole; plus chilblain vasculitic lesions of the digits linked to other vasculitic features. Moreover, discoid lupus is an unpleasant erosive and scarring skin manifestation which only partially overlapping with systemic disease but in itself representing an urgent need for treatment because of the damaging and permanent changes.[6]

In terms of internal organ involvement, renal disease is the most common and serious organ-based process. Renal lupus is graded from class I to V. Important aspects of clinical care include urinalysis for blood or protein and each clinic encounter, good blood pressure control and careful follow-up and management of any systemic activity and close involvement of the renal physicians in decisions such as the need for renal biopsy and escalation of therapy.[7]

Avoiding organ involvement including renal disease is a major objective of clinical care and may be achieved through careful monitoring and effective management in the outpatient clinic. However, once established there may be progressive loss of renal function despite biologic interventions leading to a need for renal replacement therapy or transplantation. Through unknown mechanisms, possibly the immunosuppressive effects of uraemia, lupus activity tends to decline in patients with progressive kidney disease and significant flares are uncommon in patients established on dialysis.

Neurologic involvement, although less frequent than renal lupus, represents a fascinating spectrum of clinical syndromes which may recapitulate primary autoimmune neuralgic syndromes such as myasthenia gravis, Guillain Barre and autoimmune encephalopathies.[8] These scenarios are largely clinical in their definition and recognised as lupus-related through the support of antibody testing. Multiple autoantibodies have been described in such patients. The anti-dsDNA antibodies in SLE have been shown to modulate the NMDA receptor leading to loss of regulation by glutamate, or in more specialised cases anti-neuronal antibodies such as voltage-gated potassium channels are implicated as specific to immune encephalitis limbic encephalitis (Table 111.1). A recent report describes the treatment of an anti-neurofascin–positive lupus patient with severe peripheral and autonomic neuropathy leading to total limb paralysis plus encephalopathy.[9]

Table 111.1

Autoantibody markers in SLE: correlation with clinical

AUTOANTIBODY/BIOMARKER	OVERALL PREVALENCE IN SLE	CLINICAL CORRELATE
Antinuclear Antibody (ANA)	90% plus	Usually positive at titre of 1/640 or greater
Anti-dsDNA	40%–60%	Severe disease, renal involvement, rising titre may precede clinical flare. High specificity for lupus
Anti-Smith (Sm)	20%	Severe disease, renal involvement. High specificity for lupus
Positive Crithidia staining		Supports true positive anti-dsDNA. Positive Crithidia more specific for active lupus
Anti-ro	20%	Correlates with the risk of neonatal heart block (3% of ro-positive pregnancies) and neonatal lupus. In adults subacute cutaneous lupus,

AUTOANTIBODY/BIOMARKER	OVERALL PREVALENCE IN SLE	CLINICAL CORRELATE
		to avoid PPIs in this group
Anti-phospholipid antibodies (request each of anti-cardiolipin, lupus anti-coagulant, beta2 GPI to screen)	20%	Risk of thromboembolism, risk of fetal loss. Triple positive highest risk, followed by lupus anti-coagulant

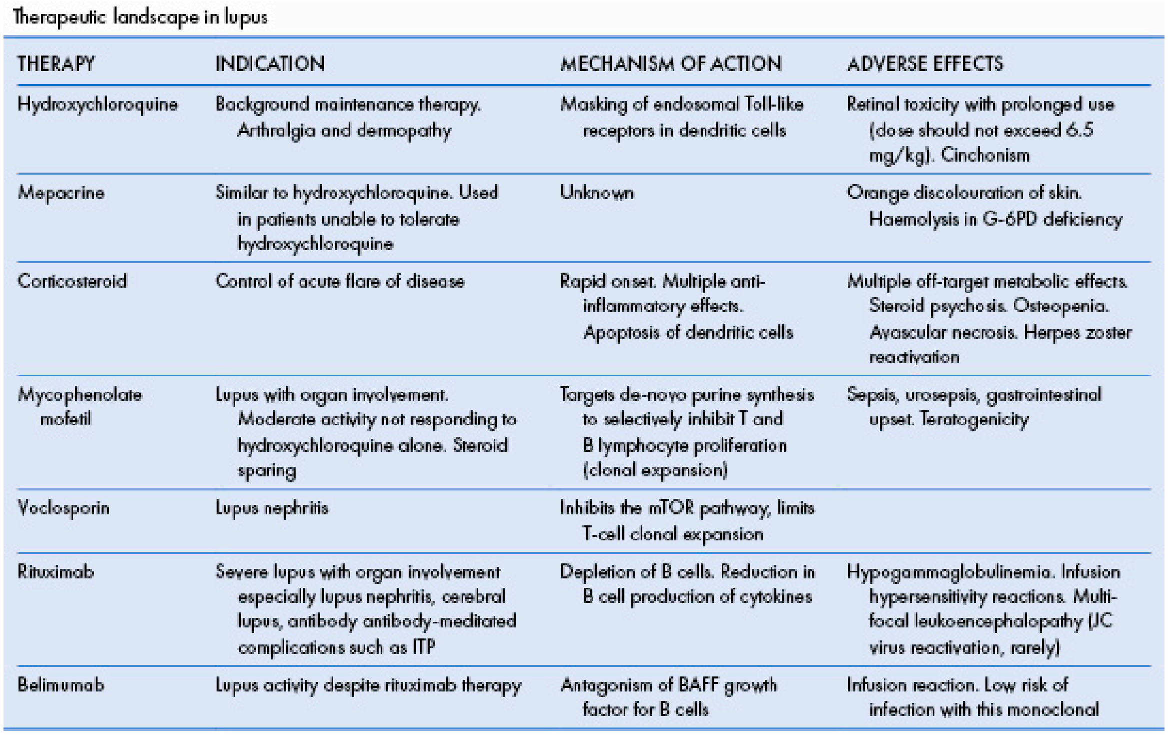
Although formal diagnostic criteria and disease activity scores have been used for inclusion in clinical trials, a more pragmatic approach to diagnosis and monitoring of activity is required. [10] In general, the presence of hallmark clinical features combined with supporting antibody markers is required for a pragmatic diagnosis of lupus and to inform management. In particular, antibody-negative disease is, in our experience, uncommon as a diagnosis and needs to be confirmed by positive tissue biopsy diagnosis, such as renal biopsy, showing classic lupus features.

Treatment Landscape

Treatments have improved for lupus and now include biologic drugs capable of inducing remission and controlling severe disease. Hydroxychloroquine remains a useful background therapy that helps to maintain remission of the disease and with minimal capacity for significant side effects. This treatment, which is believed to mask endosomal toll-like receptors and block plasmacytoid dendritic cell activation, has no link to increased susceptibility to infection. The main hazard of therapy is retinal toxicity, a form of macular pigmentation resulting in loss of central and colour vision. This complication is rare and seen with prolonged high-dose use over 6.5 mg per kg. Moreover, oral immunosuppressive drugs borrowed from the transplant field, are highly useful as disease-modifying agents with azathioprine use now superseded by mycophenolate mofetil which has fewer toxicities and demonstrable efficacy in renal and neurologic lupus, and now voclosporin therapy of proven efficacy for renal disease [11] (Table 111.2).

However, azathioprine continues to have a role as being safe for use in pregnancy, so it is common practice to switch to this agent pre-conception.

Table 111.2



Therapeutic landscape in lupus

THERAPY	INDICATION	MECHANISM OF ACTION	ADVERSE EFFECTS
Hydroxychloroquine	Background maintenance therapy. Arthralgia and dermopathy	Masking of endosomal Toll-like receptors in dendritic cells	Retinal toxicity with prolonged use (dose should not exceed 6.5 mg/kg). Cinchonism
Mepacrine	Similar to hydroxychloroquine. Used in patients unable to tolerate hydroxychloroquine	Unknown	Orange discolouration of skin. Haemolysis in G-6PD deficiency
Corticosteroid	Control of acute flare of disease	Rapid onset. Multiple anti-inflammatory effects. Apoptosis of dendritic cells	Multiple off-target metabolic effects. Steroid psychosis. Osteopenia. Avascular necrosis. Herpes zoster reactivation
Mycophenolate mofetil	Lupus with organ involvement. Moderate activity not responding to hydroxychloroquine alone. Steroid sparing	Targets de-novo purine synthesis to selectively inhibit T and B lymphocyte proliferation (clonal expansion)	Sepsis, urosepsis, gastrointestinal upset. Teratogenicity
Voclosporin	Lupus nephritis	Inhibits the mTOR pathway, limits T-cell clonal expansion	
Rituximab	Severe lupus with organ involvement especially lupus nephritis, cerebral lupus, antibody antibody-meditated complications such as ITP	Depletion of B cells. Reduction in B cell production of cytokines	Hypogammaglobulinemia. Infusion hypersensitivity reactions. Multi-focal leukoencephalopathy (JC virus reactivation, rarely)
Belimumab	Lupus activity despite rituximab therapy	Antagonism of BAFF growth factor for B cells	Infusion reaction. Low risk of infection with this monoclonal

In severe organ-threatening disease, treatment with cyclophosphamide or rituximab, a B-cell depleting anti-CD20, is indicated. [12] Although the data from clinical trials was at first disappointing, in practice rituximab therapy has demonstrated efficacy against severe life-threatening diseases and is also now used increasingly to effectively suppress disease activity in persistent moderate disease requiring recurrent courses of prednisolone. Rituximab treatment is linked to increased susceptibility to infection, including COVID-19, emerging as one of the few rheumatic drugs with this as a potential concern.

Most recently Belimumab, which targets the Blys growth factor supporting B-cell expansion, has entered routine use. Belimumab has a role in improving disease activity in chronic active disease, especially when used in combination with rituximab treatment. [13] Belimumab has the advantage of little or no risk of infection and a good safety profile plus a demonstrable ability to reduce levels of dsDNA pathogenic antibodies.

Lupus in the Intensive Care Unit

Major centres will often have inpatients with lupus admitted to ICU. The main indications would be severe active disease requiring organ support or sepsis complicating the dysregulated immunity and immunosuppressive therapy in this group. Distinguishing severe active disease from sepsis is crucial. Apart from careful clinical evaluation, indicators of underlying sepsis include elevation of the CRP not usually seen in lupus activity (lupus activity is often characterised by raised ESR with a normal CRP). Screening for sepsis should be performed in any inpatient with active lupus. Predisposing factors in these patients include reduced plasma complement levels, which impair effective IgG responses, functional hyposplenism, autoimmune leukopenia, or else occurring secondary to therapy, hypogammaglobulinaemia post rituximab or leukopenia seen in oral immunosuppressive treatments such as azathioprine or mycophenolate.

Other common management issues include background chronic steroid use such that cortisol profiling and an ACTH stimulation test should be performed on admission. Usual practice is to double the oral doses of prednisolone in ambulatory cases or switch to four times per day intravenous hydrocortisone in severely compromised or mechanically ventilated patients.

Common scenarios requiring ICU admission include severe renal involvement leading to acute kidney injury requiring haemofiltration, or significant cerebral lupus with delirium, seizures and challenging behavioural changes in an acutely unwell patient. These lupus activity-related complications can be successfully managed in ICU with a combination of specialist input from intensivists, rheumatology, renal and neurology, favouring units where all are present on site. Once sepsis has been excluded or is being effectively managed, biologic immunosuppressive regimes would generally be recommended such as rituximab in standard doses or cyclophosphamide if there is severe cerebral or renal involvement.

Significant lung involvement is less common in lupus than other connective tissue disorders such as systemic sclerosis but can manifest as pulmonary haemorrhage due to capillaritis. In this situation, plasma exchange is indicated. Other occasionally used treatments include intravenous immunoglobulin therapy (IVIG), where the main indications are as an adjunctive treatment for severe immune thrombocytopenia or significant active muscle involvement. For some of these manifestations, it is important to be aware of the expected rate of recovery, particularly in the case of cerebral lupus, where recovery is slowly achieved over weeks to months. Even patients with very adverse and severe neuro-lupus features can recover back to baseline following several months of intensive therapy.

Furthermore, overlap with anti-phospholipid syndrome (APS) should be screened for in critically ill patients. The full screen requires testing for all three of the phospholipid antibody assays: anti-cardiolipin, lupus anti-coagulant and anti-beta-2-glycoprotein. A significant positive phospholipid screen is indicated by triple positive findings of anti-cardiolipin, lupus anti-coagulant and anti-beta-2-glycoprotein testing, having the most severe clinical associations, or else positive IgG anti-cardiolipin of over 40 iU or else persistently positive lupus anti-coagulant. Severe catastrophic cases of APS require intensive therapy with a combination of anticoagulation plus immunomodulation, typically plasma exchange followed by rituximab. It is very important to involve thrombophilia specialists with experience in managing such cases. Common scenarios would include renal and splenic infarction, adrenal infarction provoking acute adrenal insufficiency, pulmonary haemorrhage or else cerebral vascular changes. Physical signs such as infarction of the auricular pinnae or digital infarcts alert to this complication.

Finally, haemophagocytic lymphohistiocytosis (HLH) is an occasional manifestation linked to severe active lupus. The management here is to aggressively control any lupus activity whilst maintaining other supportive treatments for bone marrow involvement.

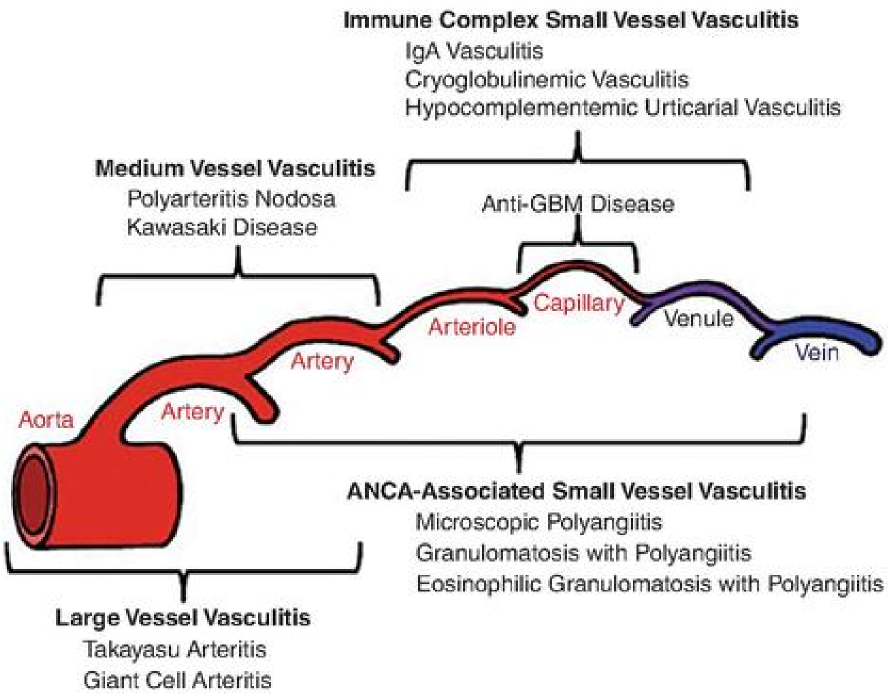
Emerging Therapies for Lupus

As well as the established treatments outlined above, emerging concepts matched to some now available treatments are anticipated to improve the outcomes for these patients. Newer therapeutics include monoclonals targeting the interferon pathways, improved and more potent B cell-depleting antibody therapies and treatments aimed at the membrane attack complement pathway linked to tissue damage in this severe autoimmune disease. [14]

Vasculitis

Background

The vasculitides are a heterogeneous group of conditions characterised by inflammation of the blood vessel wall resulting in end-organ failure or irreversible tissue damage and necrosis. Although overlap is observed between different forms of vasculitis, they are broadly divided into three subgroups according to the size of blood vessels predominantly involved: small-, medium- or large-vessel vasculitis. Small vessel vasculitides can be further subdivided according to aetiology (e.g. rheumatoid vasculitis and drug-induced vasculitis) or immunological characteristics, namely the presence of, or clinical association with, antineutrophil cytoplasmic antibody (ANCA), or the presence of immune complex deposition such as cryoglobulinaemic vasculitis or IgA vasculitis. The *2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides* (Fig. 111.2) provides an overview.[15] Rapid recognition and treatment of vasculitis is crucial for achieving the best possible outcomes for patients. This section will focus on the epidemiology, pathogenesis, clinical features and treatment of various forms of vasculitis.



Immune Complex Small Vessel Vasculitis
IgA Vasculitis
Cryoglobulinemic Vasculitis
Hypocomplementemic Urticarial Vasculitis
Medium Vessel Vasculitis
Polyarteritis Nodosa
Kawasaki Disease
Anti-GBM Disease
Capillary
Arteriole
Venule
Artery
Vein
Aorta
Artery
ANCA-Associated Small Vessel Vasculitis
Microscopic Polyangiitis
Granulomatosis with Polyangiitis
Eosinophilic Granulomatosis with Polyangiitis
Large Vessel Vasculitis
Takayasu Arteritis
Giant Cell Arteritis

The labelled diagram presents a vascular pathway exhibiting types of vasculitis based on vessel size. From left to right, the vessel sequence includes aorta, artery, arteriole, capillary, venule, and vein. The large vessel vasculitis category appears over the aorta and lists Takayasu arteritis and giant cell arteritis. The medium vessel vasculitis category is positioned over the arteries and includes polyarteritis nodosa and Kawasaki disease. The small vessel vasculitis category is divided into immune complex and A N C A associated subtypes. Immune complex small vessel vasculitis, located above the capillary and venule regions, includes I g A vasculitis, cryoglobulinemic vasculitis, and hypocomplementemic urticarial vasculitis. A N C A associated small vessel vasculitis, located beneath the arteriole and capillary, venule, and vein regions, includes microscopic polyangiitis, granulomatosis with polyangiitis, and eosinophilic granulomatosis with polyangiitis. Anti G B M disease is positioned over the capillary region.

FIG. 111.2 Distribution of vessel involvement according to the 2012 Revised International Chapel Hill Consensus Conference Nomenclature of Vasculitides. *IgA* , Immunoglobulin A; *Anti-GBM* , Anti–Glomerular Basement Membrane.

Small Vessel Vasculitis

ANCA-Associated Vasculitis

ANCA-associated vasculitis (AAV) comprises three distinct clinico-pathological syndromes: granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA) and eosinophilic granulomatosis with polyangiitis (EGPA). The overall incidence of AAVs is 20 per million per year (GPA 9 per million, MPA 9 per million, EGPA 2 per million) with a prevalence of 200 per million and an average age of onset during the seventh decade of life. [15-17] There are key similarities and differences in the manifestations, outcomes and treatments between these three disease entities. Although ANCAs are strongly implicated in the pathogenesis of AAVs, their absence does not exclude the possibility of a diagnosis of AAV. [18]

Pathogenesis of AAV is triggered by an interplay between environmental factors together with a genetic predisposition. ANCA-mediated inflammation activates pro-inflammatory cytokines and alternative complement pathways to prime neutrophils leading to the production of reactive oxygen species, release of proteolytic enzymes and the formation of neutrophil extracellular traps. Excessive NET formation is harmful to small vessels, whilst also instigating the production of ANCAs themselves, causing a vicious cycle of neutrophil extracellular traps (NET) formation and ANCA production. [19] Eosinophilic inflammation is a hallmark feature of EGPA. T-helper 2 cells produce interleukin-5 (IL-5) and type 2 innate lymphoid cells. IL-5 binds to the IL-5 receptor on eosinophils to induce eosinophilopoiesis in the bone marrow along with activation and prolonged survival of eosinophils in the tissues. [20]

GPA is associated with a cytoplasmic ANCA immunofluorescence pattern (c-ANCA), usually directed against the proteinase 3 (PR3) protein, and its clinical manifestations consist of granulomatous inflammation of the upper respiratory and lower respiratory tract and renal vasculitis. MPA, which is more commonly associated with a perinuclear ANCA immunofluorescence pattern (p-ANCA) directed against the myeloperoxidase (MPO) protein, typically involves the kidneys, lungs and peripheral nerves. Pulmonary haemorrhage can be a life-threatening manifestation of both GPA and MPA. The predominant features of EGPA are late-onset asthma, peripheral nerve vasculitis and upper airway manifestations, including chronic rhinosinusitis and nasal polyposis. All patients have peripheral eosinophilia, but ANCA positivity (usually p-ANCA directed against MPO) is only present in 50% of cases of EGPA. In EGPA, there can be overlap with other AAVs and with hyper-eosinophilic syndrome, which can be associated with gastrointestinal or cardiac involvement. [21], [22]

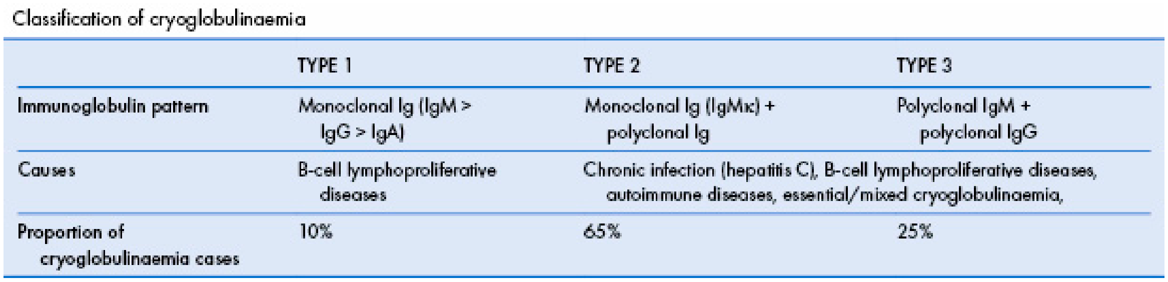
The key principle of treatment is to initiate rapid remission-induction therapy to prevent or limit organ damage; followed by maintenance of remission. In the presence of end-organ involvement, induction therapy with cyclophosphamide or rituximab, supported by glucocorticoids, is recommended. In the absence of end-organ involvement, induction therapy with disease-modifying anti-rheumatic drugs (DMARDs) such as methotrexate, azathioprine or mycophenolate are used, also in conjunction with glucocorticoids. DMARDs are also used to maintain remission, although maintenance treatment with rituximab has shown to be effective in preventing relapses. [23] In GPA and MPA, avacopan, an orally administered selective C5a receptor inhibitor, can be added alongside standard of care to limit the worsening of disease and glucocorticoid burden, therefore minimising toxicity. [24] Specifically, in EGPA, mepolizumab, a monoclonal antibody directed against IL-5, resulted in significantly higher levels of sustained remission in EGPA, compared to placebo, thus allowing for reduced glucocorticoid use. [25] The use of plasma exchange in severe AAV, sometimes considered with serum creatinine levels of ≥500 mmol/L due to rapidly progressive glomerulonephritis, or in severe diffuse alveolar haemorrhage, has fallen out of favour following evidence it did not reduce the incidence of death or end-stage renal disease. [26]

Almost half of the patients with AAV relapse within the first three years of achieving remission. Many patients fail to achieve remission within the first six months of remission-induction therapy due to persistent disease activity. [27] This can increase the risk of glucocorticoid burden and toxicity.

Cryoglobulinaemic Vasculitis

Cryoglobulinaemia refers to the presence of cryoglobulins in the serum. These are immunoglobulins that precipitate when exposed to temperatures below 37°C and re-solubilise when re-warmed. Cryoglobulinemic vasculitis is the deposition of these cold-precipitating immunoglobulins in small blood vessels causing vascular inflammation and tissue damage. Patients may present with cutaneous vasculitic lesions, arthralgia, peripheral neuropathy and renal involvement, although some patients may not have any symptoms at all. [28] Cryoglobulinaemia can be classified into three categories: type 1, type 2 and type 3 (the latter two are known, in combination, as mixed cryoglobulinaemia) – outlined in Table 111.3 . [29]

Table 111.3



Classification of cryoglobulinaemia

	TYPE 1	TYPE 2	TYPE 3
Immunoglobulin pattern	Monoclonal Ig (IgM > IgG > IgA)	Monoclonal Ig (IgMκ) + polyclonal Ig	Polyclonal IgM + polyclonal IgG
Causes	B-cell lymphoproliferative diseases	Chronic infection (hepatitis C), B-cell lymphoproliferative diseases, autoimmune diseases, essential/mixed cryoglobulinaemia,	
Proportion of cryoglobulinaemia cases	10%	65%	25%

Mechanisms of disease in cryoglobulinaemic vasculitis are thought to be related to both blood stasis due to hyperviscosity and immune-mediated processes. Hyperviscosity leads to occlusion of small and medium blood vessels due to cryoglobulin precipitation, causing symptoms of hyperviscosity syndrome which can include a plethora of symptoms such as headache, dizziness, blurred vision, hearing loss, epistaxis, livedo reticularis, Raynaud's, acrocyanosis, cutaneous necrosis and distal ulcers. These symptoms usually occur or worsen during cold exposure and are more common in type 1 cryoglobulinemia. [30] Immune-mediated vasculitis of small and medium blood vessels is more common in mixed cryoglobulinaemia. Much of the understanding of immune-mediate mechanisms is through observation of hepatitis C in the pathogenesis of cryoglobulinaemia. IgM with RF activity (as autoantibody) binds to IgG (as antigen) to form immune complexes, which deposit on the vessel wall, activating the complement system through the classical pathway, leading to vasculitis. In addition, monoclonal IgG3 in type I cryoglobulinemia spontaneously self-aggregates by non-specific Fc-Fc interaction and then depositing on the vascular wall. The self-aggregated monoclonal IgG3 binds to C1q via the CH2 domain on its heavy chain, again activating the complement system to cause vasculitis. Blood tests often demonstrate hypocomplementaemia, raised rheumatoid factor and raised C1q levels. [30], [31] The prevalence of cryoglobulinemic vasculitis is rare (1:100,000) with significant geographic variations. It is commonly seen in patients aged 45 to 65 years with a maximum incidence in women (sex ratio is 2–3:1). The disease is more common in southern Europe, which might be related to the endemic prevalence of hepatitis C. 20% to 50% of patients with hepatitis C can have serum cryoglobulins, with only up to one-third of these patients developing cryoglobulinaemic symptoms. Renal involvement in cryoglobulinaemic vasculitis takes the form of membranoproliferative glomerulonephritis, characterised histologically by subendothelial and mesangial immune deposits. Treatment of cryoglobulinaemic vasculitis involves targeting the underlying cause, typically alongside the initiation of glucocorticoids. [32]

Medium-Vessel Vasculitis

Polyarteritis Nodosa

Polyarteritis nodosa (PAN), a multi-systemic necrotising medium-vessel vasculitis closely associated with hepatitis B and C infections, has become a rare disease with effective immunisation of hepatitis B and eradication treatments for hepatitis C. The prevalence of PAN is in the region of 2.6–14 per million adults and the incidence is between 0.6 and 3.6 per million adults. [33], [34] Presenting features may include: necrotic ulcers, livedo reticularis, mononeuritis multiplex, ischaemic strokes, renal insufficiency (renal artery stenosis and thrombosis leading to infarction) with associated hypertension, coronary artery involvement, pericarditis, abdominal pain due to mesenteric artery involvement leading to mesenteric ischaemia and bowel perforation, testicular pain, myalgia and arthralgia. Lung involvement is rare in PAN. Aneurysmal disease observed on angiograms has been described as a ‘rosary sign’, akin to beads of a rosary. [35]

It is thought that the pathogenesis differs between hepatitis B-induced PAN and idiopathic PAN. The former results from direct injury to the blood vessel wall from hepatitis B surface antigen and antibody immune complexes which, in turn, activate the complement cascade, thus recruiting and activating neutrophils. This tends to occur within six months of acute hepatitis B infection and is associated with hypocomplementaemia due to complement consumption resulting from immune complex deposition. Idiopathic PAN is thought to be driven by an underlying immunological mechanism associated with elevated levels of IL-2, IL-8, IFN-γ, TNF-α and IL-1β, however, the precise pathogenesis is unknown. [36]

The mainstay of management involves the treatment or eradication of the underlying cause, such as hepatitis B or C, alongside immunosuppressive therapy with glucocorticoids and disease-modifying agents such as methotrexate, escalating to rituximab or cyclophosphamide in severe, organ-threatening disease. There is also a role for plasma exchange to remove immune complexes which initiate and perpetuate the disease process. The five-year survival rate is 80% with treatment and 13% without treatment. Death is usually due to renal failure, myocardial infarction or stroke.[37]

Large-Vessel Vasculitis

Giant Cell Arteritis

Giant cell arteritis (GCA), also known as temporal arteritis, is the most common primary systemic vasculitis; 1 in 4500 individuals are diagnosed per year with an incidence of 2.2 per 10,000 patient-years. It is three times more common in females compared to males, and more commonly observed in those of northern European descent. Peak incidence is seen in the eighth decade of life and the condition is very rare in those under 50 years old.[38] It is a form of granulomatous arteritis with a predilection for the branches of the carotid artery, including the temporal, ophthalmic, facial, occipital and lingual arteries. The pathogenesis is thought to involve toll-like receptors on immature dendritic cells in the adventitia of the artery wall sensing an infectious agent or autoantigen. Activated dendritic cells then produce pro-inflammatory cytokines such as IL-1, IL-6, IL-18 and TNFα, as well as processing the antigen and presenting it to $CD4^+$ T cells. In turn, this activates T cells and the production of Th1 and Th17 cells, ultimately leading to a mixed inflammatory infiltrate and multinucleate giant cells.[39]

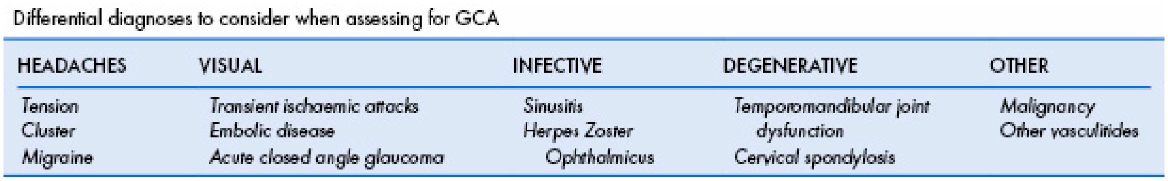
The symptomatic presentation of GCA is heterogenous and can include the following: headaches, visual disturbance (including blurred vision and painless unilateral or bilateral visual loss), jaw claudication, tongue claudication, polymyalgia rheumatica (PMR), scalp tenderness, weight loss, fevers and fatigue. Symptoms typically present acutely, however, a subacute presentation is not uncommon. Signs may include tender, reduced or absent temporal or facial artery pulses, reduced visual acuity, visual field defects, ophthalmoplegia, optic disc oedema, scalp tenderness, significant blood pressure differences between both arms, carotid bruits, polymyalgic pattern of stiffness and reduced or absent radial arteries. About 30%–50% of those with untreated GCA will develop permanent and severe loss of vision in one eye. Without immediate treatment, about a third of these individuals will go on to develop sight loss in the contralateral eye, often within a week of the first eye.[40] Causes of visual loss in GCA are summarised in Table 111.4 . Up to 50% of patients with GCA will have PMR. About 10 to 15% of those with pre-existing PMR develop GCA.[41] Whilst assessing patients for GCA, it is important to consider other important differential diagnoses (Table 111.5).

Table 111.4

Causes of visual loss in GCA

MANIFESTATION	*PREDOMINANT SYMPTOM*
Anterior ischaemic optic neuropathy *Anaurosis fugax* *Cilioretinal artery occlusion* *Central retinal artery occlusion* *Posterior ischaemic optic neuropathy*	*Acute unilateral visual loss* *Bilateral visual loss in one-third of patients if left untreated*
Cranial neuropathy	*Diplopia* *Ophthalmoplegia* *Anisocoria* *Ptosis*

Table 111.5



Differential diagnoses to consider when assessing for GCA

HEADACHES	VISUAL	INFECTIVE	DEGENERATIVE	OTHER
Tension Cluster Migraine	Transient ischaemic attacks Embolic disease Acute closed angle glaucoma	Sinusitis Herpes Zoster Ophthalmicus	Temporomandibular joint dysfunction Cervical spondylosis	Malignancy Other vasculitides

Inflammatory markers are usually raised, although up to 3% of cases confirmed as GCA with further investigations have a normal CRP. ESR can also be useful, although frequently this is raised due to older age, so may not be a reliable marker of arteritic inflammation. Temporal artery biopsy was once regarded as the gold-standard, first-line investigation (positive features include mixed inflammatory cell infiltrate in the media, multinucleate giant cells and thickened media and intima with associated luminal narrowing), however, its invasiveness and reliance upon adequate length of sampling of at least 0.5–1 cm, to mitigate for the patchy disease process known as skip lesions, has led to the emergence of temporal artery ultrasound as a first-line diagnostic test. [42] A non-compressible ‘halo sign’, a dark hypoechoic area around the vessel lumen representing vessel wall inflammation, is 87% sensitive and 96% specific for diagnosing GCA. Large-vessel vasculitis in GCA is observed in up to 80% of cases. Known as extra-cranial GCA or large-vessel–GCA, it involves the aorta and its major branches. Imaging modalities used to diagnose large-vessel–GCA include computed tomography angiography (CTA), magnetic resonance angiography (MRA) or a combination of positron emission tomography (PET) and CT, known as PET-CT, which uses a [fluorine-18] fluorodeoxyglucose (^{18}F-FDG) radiotracer. [43]

The mainstay of treatment involves initiating high-dose glucocorticoids with a tapering regime (Table 111.6). Methylprednisolone doses of 500 to 1000 mg may be used in cases of visual loss or amaurosis fugax. Concomitant bone protection (anti-resorptive treatment with bisphosphonate or denosumab, plus cholecalciferol) and gastroprotection with a protein pump inhibitor or histamine H^2 receptor antagonist should be started alongside glucocorticoid therapy. In cases of relapsing or refractory disease, methotrexate and/or tocilizumab can be used to maintain disease remission. [44]

Table 111.6

Glucocorticoid tapering regime

DOSE (mg)	DURATION
60 (starting point in visual disease or jaw claudication)	*Until symptoms and inflammatory markers resolved; usually 4 weeks.*
50	*2 weeks*
40 (starting point in uncomplicated disease)	*If starting point: until symptoms and inflammatory markers resolved; usually 4 weeks.* *If not starting point (i.e. commenced 60 mg) then give for 2 weeks.*
30	*2 weeks*
20	*2 weeks*
17.5	*2 weeks*
15	*2 weeks*
12.5	*2 weeks*
10	*4 weeks (then reducing by 1 mg every 4 weeks until discontinued)*

Takayasu Arteritis

Takayasu arteritis (TAK) is a rare form of granulomatous arteritis affecting the aorta, and its major branches, and pulmonary arteries, predominantly affecting younger adults in the second and third decades of life. [45] Also known as ‘pulseless disease’, many patients develop arterial narrowing, occlusion, or aneurysmal disease. It is more common in Asian populations with a prevalence of 40 per million in Japan compared to 4.7–13.3 per million in Europe. [46], [47] It is almost 10 times more common in females compared to males. [47] TAK shares some pathophysiological features with large-vessel–GCA, and imaging modalities also include CTA, MRA and PET-CT. The mainstay of treatment involves early initiation of glucocorticoids and DMARDs, with escalation to cyclophosphamide or tocilizumab if the treatment response is incomplete. Vascular reconstructive surgery, endovascular or open surgical intervention, may be required in progressive disease despite maximal medical therapy.

Vasculitis in the Intensive Care Unit

Given the vastly heterogeneous nature of the vasculitides, the key challenges in the intensive care unit are early diagnostic accuracy, differentiating severe active autoimmune disease from sepsis and prompt initiation of treatment. Sometimes the first presentation of acute severe vasculitis leads to an ICU admission, therefore intensifying the need for collaborative, multidisciplinary efforts to address these diagnostic and treatment challenges.

Most cases of acute severe vasculitis will manifest with generalised constitutional unwellness, prompting an extensive septic screen and, at times, broad-spectrum empirical antibiotic treatment. Indeed, in patients with a prior diagnosis of vasculitis on active immunosuppressive treatment who become non-specifically and critically unwell, it is imperative that an underlying source of infection (including atypical infection) is ruled out prior to escalating immunosuppression. Careful clinical assessment for, and identification of, localising features of life-threatening vasculitis invariably changes the treatment paradigm away from antimicrobial therapy to intense immunosuppression.

Life-threatening clinical manifestations vary between the different forms of vasculitis. Small vessel vasculitis can result in respiratory failure, acute kidney injury and heart failure, all of which can result in the need for organ support in the intensive care unit. In AAV, particularly GPA and MPA, respiratory failure due to diffuse alveolar haemorrhage (bleeding from the pulmonary microcirculation into the alveolar spaces) usually presents with dyspnoea, hypoxia, acute anaemia and diffuse infiltrative opacifications on chest imaging. Rapidly progressive glomerulonephritis (RPGN), histologically pauci-immune necrotising glomerulonephritis with extensive glomerular crescent formation, can lead to acute renal dysfunction requiring haemofiltration in the ICU. Acute myopericardial disease is a life-threatening feature of EGPA presenting with acute cardiac dysfunction, usually characterised by dyspnoea, chest pain, raised biomarkers such as troponin I and NT-proBNP and imaging features of ventricular dysfunction and myopericarditis on echocardiography or cardiac MRI.

PAN, a medium-vessel vasculitis, can cause life-threatening organ involvement requiring intensive care support, including acute kidney injury due to stenotic or thrombotic infarction, myocardial infarctions due to coronary artery involvement and abdominal manifestations such as mesenteric ischaemia and bowel perforation. TAK can manifest in acute aneurysmal rupture, aortic dissection or vascular occlusion leading to significant morbidity or mortality.

Despite the breadth of clinical manifestations across the vasculitides, the mainstay of treatment across the board involves high-dose glucocorticoids (in the form of intravenous methylprednisolone) with rituximab or cyclophosphamide to gain disease control. In refractory small vessel vasculitis, particularly with concomitant infection, IVIg is used to support disease remission. Plasma exchange remains an option in PAN, although has fallen out of favour in recent times for AAV. The need for haemofiltration, ventilation or ionotropic support depends upon the presence and nature of organ failure. Early cross-speciality input, to support intensivists and rheumatologists, is crucial and can range from renal, respiratory, cardiology, vascular and general surgical expertise depending on the clinical features.

Haemophagocytic Lymphohistiocytosis

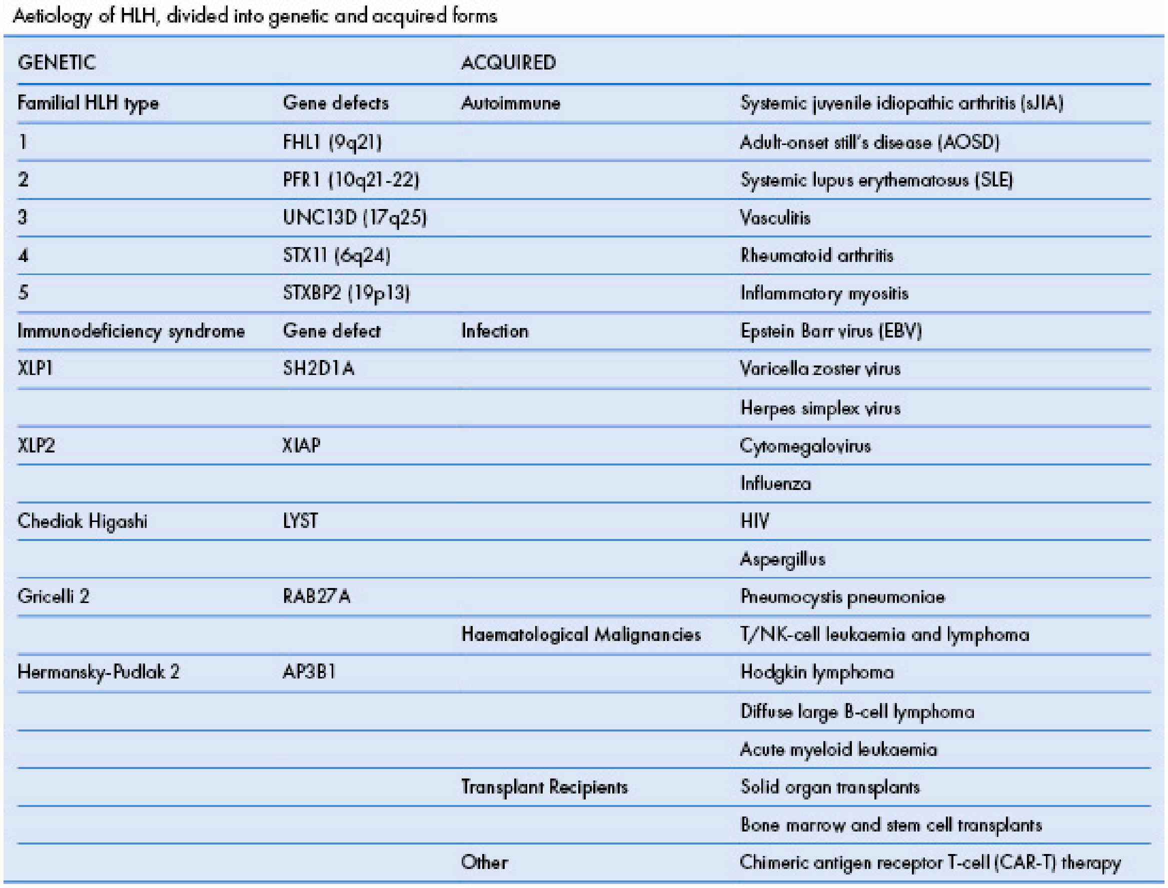
Background

Haemophagocytic lymphohistiocytosis (HLH) is a rare but potentially fatal condition driven by aggressive and accelerated immune hyperactivity. It is observed in all age groups and can be driven by underlying genetic susceptibility, malignancy, infection, or autoimmune and autoinflammatory disease. [48] Early recognition and prompt initiation of treatment is paramount in HLH, with treatment delays (often due to delays in diagnosis) significantly reducing the likelihood of a successful outcome. Loss of immune regulation leads to excessive macrophage and T-cell activation, causing an uncontrolled state of self-perpetuating hyperinflammation, often described as a cytokine storm. [49]

Causes of HLH

There remains a need for wider consensus on HLH terminology; however, broadly speaking it can be divided into familial HLH which is due to inherited genetic defects, and secondary (or acquired) HLH occurring because of autoimmune or autoinflammatory disease, malignancy, infection and immunocompromise in transplant recipients. The term macrophage activation syndrome (MAS) is often used for HLH specifically due to autoimmune or autoinflammatory disease. With HLH terminology in mind, causes can be categorised as shown in Table 111.7 . [50]

Table 111.7



Aetiology of HLH, divided into genetic and acquired forms

GENETIC		ACQUIRED	
Familial HLH type	Gene defects	Autoimmune	Systemic juvenile idiopathic arthritis (sJIA)
1	FHL1 (9q21)		Adult-onset still's disease (AOSD)
2	PFR1 (10q21-22)		Systemic lupus erythematosus (SLE)
3	UNC13D (17q25)		Vasculitis
4	STX11 (6q24)		Rheumatoid arthritis
5	STXBP2 (19p13)		Inflammatory myositis
Immunodeficiency syndrome	Gene defect	Infection	Epstein Barr virus (EBV)
XLP1	SH2D1A		Varicella zoster virus
			Herpes simplex virus
XLP2	XIAP		Cytomegalovirus
			Influenza
Chediak Higashi	LYST		HIV
			Aspergillus
Gricelli 2	RAB27A		Pneumocystis pneumoniae
		Haematological Malignancies	T/NK-cell leukaemia and lymphoma
Hermansky-Pudlak 2	AP3B1		Hodgkin lymphoma
			Diffuse large B-cell lymphoma
			Acute myeloid leukaemia
		Transplant Recipients	Solid organ transplants
			Bone marrow and stem cell transplants
		Other	Chimeric antigen receptor T-cell (CAR-T) therapy

HLH is most prevalent in systemic juvenile idiopathic arthritis (sJIA), occurring in almost 1 in 10 cases. On the same continuum of autoinflammatory disease, adult-onset Still's disease (AOSD) is also recognised as a common trigger of HLH, again affecting almost 1 in 10 patients. [50], [51] SLE accounts for a significant number of cases of acquired HLH, not least due to the prevalence of the disease, with the risk of poor outcomes, including mortality, being highest during an SLE flare. [52] Infections in themselves (such as acute EBV) can cause HLH and also can act as a causative trigger of HLH in patients with underlying autoimmune disease or immunocompromise.

Pathophysiology

HLH is essentially a self-perpetuating hyperinflammatory state, sometimes termed a cytokine storm, resulting from the abnormal cytolytic function of natural killer cells and cytotoxic T cells, leading to an inability to eliminate the antigenic triggers from infection, malignancy and autoimmune and autoinflammatory disease. Antigen-presenting cells and regulatory T cells are overcome by the proliferation and perpetuation of activated cytotoxic T cells, in turn inducing activation and proliferation of tissue macrophages, also known as histiocytes. Activated histiocytes undergo haemophagocytosis, hence the term HLH, causing a cytokine storm which induces fevers and a generalised hyperinflammatory state. [49]

With specific regard to autoinflammatory disease (such as AOSD or sJIA), HLH may also be propagated by innate immune system pathways, including IL-1, the blockade of which forms part of the mainstay of treatment, which gives rise to a systemic inflammatory response. Gain of function mutations may even contribute to the activation of IL-1, further increasing the potentiation of disease. Viral triggers are often thought to play a role in autoimmune- and autoinflammatory-driven HLH. [51]

Clinical features

In a patient with features consistent with sepsis not improving with standard of care, HLH needs to be considered. Unremitting fevers in a patient with risk factors (e.g. underlying autoimmune disease or malignancy), with a ferritin greater than 10,000 is consistent with HLH and should be investigated and treated promptly. The *HScore* not only serves as a useful tool to provide an estimate of how likely a patient has HLH but also summarises the key clinical features (Table 111.8). Patients may also present with headaches, confusion, coma and seizures, in the context of multi-organ failure. [53]

Table 111.8

HScore – A validated tool to quantify the likelihood of HLH

Clinical Feature		Points
Immunosuppression	No	0
	Yes	18
Temperature	<38.4°C	0
	38.4–39.4°C	33
	>39.4°C	49
Organomegaly	No	0
	Hepatomegaly or splenomegaly	23
	Hepatomegaly and splenomegaly	38
Cytopenias	1 lineage	0
	2 lineages	24
	3 lineages	34
Ferritin (ng/mL)	<2000	0
	2000-6000	35
	>6000	50
Triglycerides (mmol/dL)	<1.5	0
	1.5 – 4	44
	>4	64
Fibrinogen (g/L)	>2.5	0
	≤2.5	30
AST (U/L)	<30	0

Clinical Feature		Points
	≥30	19
Haemophagocytosis on bone marrow aspirate	No	0
	Yes	35

The probability of HLH incrementally rises with every 10-point increase in the HScore, ranging from ≤90 (diagnostic probability of <1%) to ≥241 (diagnostic probability of >99%). [54] Coagulopathy is usually observed with hypofibrinogenaemia, raised D-dimer and an acute drop in ESR (in the context of a raised CRP), indicating a consumptive coagulopathy. Elevated levels of soluble CD25, low or absent natural killer cell activity and high levels of soluble IL-2 receptor are also recognised features but not frequently tested. [55]

Treatment in the Intensive Care Unit

Invariably, patients with HLH are critically ill. Without early initiation of aggressive and effective treatment, HLH is usually fatal. Late detection, or failure to detect, the disease significantly increases the chances of mortality. The mainstay of treatment, outlined in Table 111.9 , for HLH secondary to autoimmune and autoinflammatory disease, involves early suppression of hyperinflammation, whilst also identifying and eliminating any specific triggers such as infections. [50] , [56]

Table 111.9

An approach to early treatment of HLH secondary to autoimmune and autoinflammatory disease

First line	Intravenous methylprednisolone 1 g daily for 3 to 5 days and Anakinra up to 8 mg/kg/day (by subcutaneous injection or intravenous infusion) titrated to clinical response
Second line	Intravenous immunoglobulin 2 g/kg for 3 to 5 days
Third line (if refractory to first and second lines)	Ciclosporin 2 to 7 mg/kg/day Further high-dose steroids Further higher dose of anakinra Further intravenous immunoglobulin (14 to 21 days after the previous cycle)
Fourth line	Etoposide 150 mg/m^2 twice weekly for 2 weeks then once weekly for 6 weeks, discussion with haemato-oncology recommended
Other	Rituximab is considered in cases of concurrent EBV

The treatment approach for HLH secondary to malignancy usually involves targeting the primary disease with the appropriate anti-cancer treatment whilst controlling the cytokine storm using some treatment modalities outlined in Table 111.9 .[50]

Prognosis

Prognosis in HLH is broadly poor and depends upon the underlying aetiology. Early recognition and prompt treatment may reduce the risk of significant morbidity or mortality. The mortality rate from acquired forms of HLH, including autoimmune aetiologies, is up to 40%. The mortality rate of cancer-associated HLH is up to 80%. There are several factors associated with a poorer prognosis, including peak ferritin level, need for intensive care admission, marked cytopenia, older age and presence of underlying malignancy. In those with malignancy-driver HLH, the presence of a viral trigger further worsens the chances of survival. Specifically in patients with SLE, those identified as having HLH, approximately one-third of cases are fatal.[57]

Blood transfusion and patient blood management

Craig French, Zoe McQuilten and James Winearls

Blood component therapy has a central therapeutic role in clinical medicine [1–3] ; PBM is an evidence-based approach, which, by clinically managing and preserving a patient's blood, aims to optimise patient outcomes. [4] The demand for blood components continues to increase consequent to the greater burden of disease due to an ageing population.

When prescribing blood component therapy, the clinical problem and the patient's needs must be accurately identified and clearly understood. Blood component therapy is often required whilst the basic disease process is corrected (e.g. surgical control for acute haemorrhage, or support for bone marrow suppression until the marrow recovers). Therapy is aimed at controlling the effects of a deficiency (e.g. anaemia, thrombocytopaenia and hypogammaglobinaemia) or preventing secondary complications. Alternatively, the indication is passive immunotherapy (e.g. Rhesus prophylaxis) or high-dosage intravenous immunoglobulin as immunomodulatory therapy.

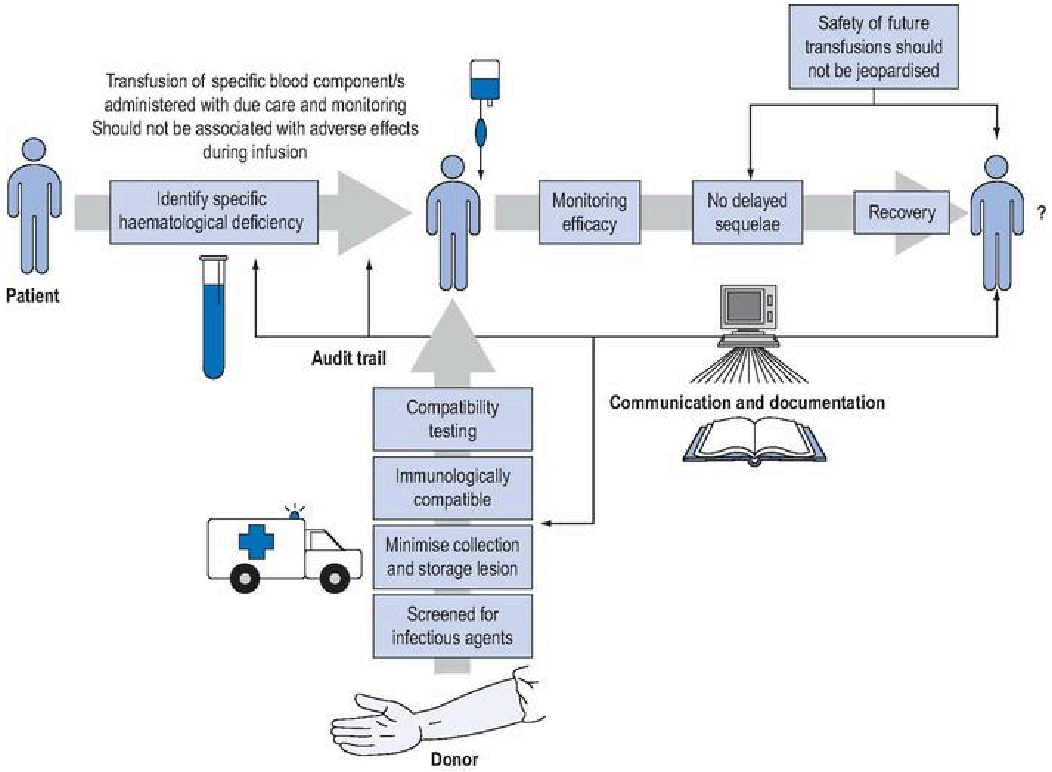
The Transfusion Decision

The role of blood transfusion in a wide range of clinical settings has been critically reassessed, especially in relationship to blood components (red cells, platelet concentrates, fresh frozen plasma, cryoprecipitate). Careful risk assessment and the use of blood conservation techniques substantially reduced the need for transfusion in many elective surgical settings. Whilst transfusions may be lifesaving, blood transfusion has known risks and observational studies have demonstrated an association between blood component therapies and adverse patient outcomes. Consequently, it is appropriate that there remains a focus on techniques to minimise exposure.

In the 20th century, many clinicians assumed transfusion of blood components was always beneficial and had limited knowledge of the potential harms.[5, 6] If allogeneic blood component therapy can be avoided, the potential hazards cease to be an issue. The decision to transfuse blood components can be challenging, the indications are controversial or unclear and in haemodynamically stable patients, the evidence of benefit is uncertain. It is therefore reasonable to adopt a position that questions the clinical need for each transfusion.[7, 8] Potential hazards must be balanced against benefits and wherever possible the benefits and risks should be explained to the patient/relatives.

In considering the use of allogeneic blood transfusion, the following questions need to be addressed to provide for safe and effective transfusion (Fig. 112.1):

- What is the timeframe of the decision-making process?
- Is it an elective decision?
- What is the most appropriate therapy for the patient?
- Are there alternatives to allogeneic transfusion?
- What component is indicated and where should it be obtained?
- Except for serological compatibility are there any other patient-specific requirements (e.g. irradiated and cytomegalovirus [CMV]-negative).
- How should the component be administered and monitored?
- What are the potential hazards of blood component therapy?
- Can the risk of adverse effects be avoided or minimised?
- Is the patient fully informed of the medical decisions?
- Early diagnosis and prompt management of adverse events.
- What is the cost of the transfusion therapy?



Safety of future transfusions should not be jeopardised
Transfusion of specific blood component/s administered with due care and monitoring Should not be associated with adverse effects during infusion
Patient
Identify specific haematological deficiency
Monitoring efficacy
No delayed sequelae
Recovery
?
Audit trail
Communication and documentation
Compatibility testing
Immunologically compatible
Minimise collection and storage lesion
Screened for infectious agents
Donor

The flow diagram depicts a transfusion process beginning with a donor at the bottom and ending with a recovering patient at the top right. The donor arm leads to a sequence of steps including screening for infectious agents, minimising collection and storage lesions, ensuring immunological compatibility, and conducting compatibility testing. These steps form part of an audit trail. Blood is collected and tested, then linked to a patient with a specific haematological deficiency. The transfusion is administered with care and monitoring to avoid adverse effects. Following infusion, the process involves monitoring efficacy, ensuring no delayed sequelae, and achieving recovery. A message states that the safety of future transfusions should not be jeopardised. Communication and documentation connect all stages through a central icon of a computer and an open book.

FIG. 112.1 What is a safe transfusion?

Clinical Guidelines for Blood Component Therapy

The following is a brief summary of the clinical guidelines for the use of commonly used blood components. The use of specific concentrates or recombinant products is beyond the scope of this chapter. As alluded to, there is a shift in the current development of clinical practice guidelines from focusing on specific indications for blood components to a problem-oriented understanding of the clinical issues (i.e. PBM). [9], [10]

Red Cell Transfusions

It is challenging to define what appropriate use of red cell transfusions is in acute medicine; in the absence of a major haemorrhage, it may be difficult to identify the benefits of red cell transfusion. A clinician must consider guidance as it applies to an individual patient. The transfusion decision is not based on red cell concentration alone: relying on a single trigger may be appropriate for some patients but potentially hazardous in others. [11], [12]

In critically ill patients who are not actively bleeding or have acute myocardial infarction, [13] a restrictive transfusion strategy should be employed. Guidelines recommend that for most patients:

- Red cell transfusion is generally unnecessary when the haemoglobin concentration is greater than 90 g/L. [10]
- When haemoglobin concentration is in the range of 70–90 g/L, the decision to transfuse should be based on the patient's clinical condition.

- Red cell transfusion is likely appropriate when the haemoglobin concentration is less than 70 g/L and the anaemia is not reversible with specific therapy; however, lower levels may be acceptable in well-compensated patients, especially in the younger age group.[6]

When red cell transfusion is indicated, a single unit followed by clinical reassessment is advised.[10,14]

Platelet Transfusions

Platelet transfusion therapy may benefit patients with platelet deficiency or dysfunction. The following are the indications for platelet transfusions.[10]

Prophylaxis

- In a critically ill patient without bleeding when the platelet count is $<20 \times 10^9$/L.
- To maintain the platelet count at $>50 \times 10^9$/L in patients undergoing surgery or invasive procedures.[15]
- In qualitative platelet function disorders, depending on clinical features and setting (platelet count is not a reliable indicator for transfusion).

Bleeding Patients

- In any haemorrhaging patient in whom thrombocytopaenia secondary to marrow failure is considered a contributory factor.[16]
- When the platelet count is $<50 \times 10^9$/L in the context of massive haemorrhage/transfusion and $<100 \times 10^9$/L in the presence of diffuse microvascular bleeding.

The transfusion of platelet concentrates is not generally considered appropriate:

- when thrombocytopenia is due to immune-mediated destruction

- in thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome
- in uncomplicated cardiac bypass surgery.

Fresh Frozen Plasma

There are few specific indications for fresh frozen plasma.[17], [18] Its use may be appropriate:

- for the replacement of single-factor deficiencies where a specific or combined factor concentrate is not available
- for treatment of the multiple coagulation deficiencies associated with acute systemic coagulopathies:
  - disseminated intravascular coagulation (DIC)
  - massive blood transfusion
  - trauma-induced coagulopathy
  - cardiac bypass surgery
  - liver disease
  - peri partum coagulopathies
  - venom-induced coagulopathies.
- for treatment of inherited deficiencies of coagulation inhibitors in patients undergoing high-risk procedures where a specific factor concentrate is unavailable
- for immediate reversal of warfarin-induced anticoagulation in the presence of potentially life-threatening bleeding when prothrombin complex concentrates (PCCs) are not available.

The use of fresh frozen plasma is generally not considered appropriate in cases of:

- hypovolaemia
- plasma exchange procedures unless post-exchange invasive procedures are planned or there is a specific indication for replacement such as thrombotic thrombocytopaenic purpura
- treatment of immunodeficiency states.

Cryoprecipitate

Whole blood-derived cryoprecipitate is prepared from freshly collected plasma and was originally developed for the treatment of haemophilia due to factor VIII deficiency. Cryoprecipitate has a high concentration of fibrinogen, however, there can be considerable variability in content [388 mg±−125 mg/unit]. [19-21] In addition, cryoprecipitate contains FVIII, vWF, F-XIII, fibronectin, antithrombin and alpha-2 antiplasmin. [22] Cryoprecipitate is stored at −25°C and is available in all ABO groups. ABO compatibility with the patient's red cells is preferred, or else AB universal donor or cryoprecipitate of a group that has been tested and found to contain a low titre of haemolytic antibodies to the recipient's red cells (e.g. A cryoprecipitate for a B recipient). Despite the acceptance of cryoprecipitate for fibrinogen replacement in acquired coagulopathy, there remains a lack of Level 1 evidence to support its use in the context of critical bleeding. In Australia, cryoprecipitate is prepared from plasma derived from whole blood or apheresis donations; one unit of apheresis cryoprecipitate is equivalent to approximately 2.5 units of whole blood-derived cryoprecipitate.

Fibrinogen Concentrate

Fibrinogen concentrate (FC) is a lyophilised coagulation factor concentrate made from pooled plasma. There are a number of theoretical advantages in using FC for fibrinogen replacement; standard fibrinogen dose per vial, reduced volume, viral inactivation, no requirement for ABO compatibility matching, long shelf-life, and ease of transport, reconstitution and administration. At present, the use of FC compared to cryoprecipitate in acquired bleeding is not supported by high-quality evidence. [23] One of the major potential advantages of FC is the rapid time to delivery of fibrinogen, as it can be stored in the point-of-care environment, where it can be rapidly reconstituted and administered. [24] Disadvantages of FC include lack of other factors present in cryoprecipitate, potentially different side effect profiles (e.g. thrombotic events), and, in many countries, significantly higher costs (e.g. in Australia 1g FC $1000 Australian Dollars compared to

$328 for equivalent dose of cryoprecipitate – (Australian National Blood Authority Product List). Differences in coagulation factor levels between FC and cryoprecipitate are important, as these may have implications on their effect on clot formation, clot stability and resistance to clot lysis.[25] There are a number of ongoing clinical trials investigating the role of both FC and cryoprecipitate in critical bleeding.[26]

Immunoglobulin

Immunoglobulin replacement with intravenous or subcutaneous immunoglobulin (IVIg or SCIg) is indicated for the prevention of infection in patients with primary or secondary hypogammaglobulinaemia.[27,28] High-dose IVIg is used as an immunomodulatory treatment for a number of conditions (Chapter 110). It is recommended as an adjunctive therapy for toxic shock syndrome caused by group A streptococci or *Staphylococcus aureus*[27,29]; however, the routine use of immunoglobulin therapy in septic shock is not advised. High-dose IVIg also has a role in some autoimmune disorders, such as idiopathic thrombocytopenic purpura, autoimmune polyneuropathy and others.

Factor Concentrates

There is an increasing number of plasma protein concentrates available for clinical use. Some are prepared from donor plasma and some by recombinant technology. Factor VIII and factor IX concentrates have an established role in the management of haemophilia, but others are in the process of establishing their clinical efficacy and indications. Antithrombin III (ATIII) concentrates are available for thrombophilia due to ATIII deficiency and have been recommended in other disorders where ATIII may be depleted (e.g. DIC and MOF) but evidence for efficacy is sparse.[30] Recombinant human-activated protein C has antithrombotic, anti-inflammatory and profibrinolytic properties. Clinical trials of activated protein C in severe sepsis did not demonstrate a consistent beneficial effect. Accordingly, its use is no longer recommended.[31]

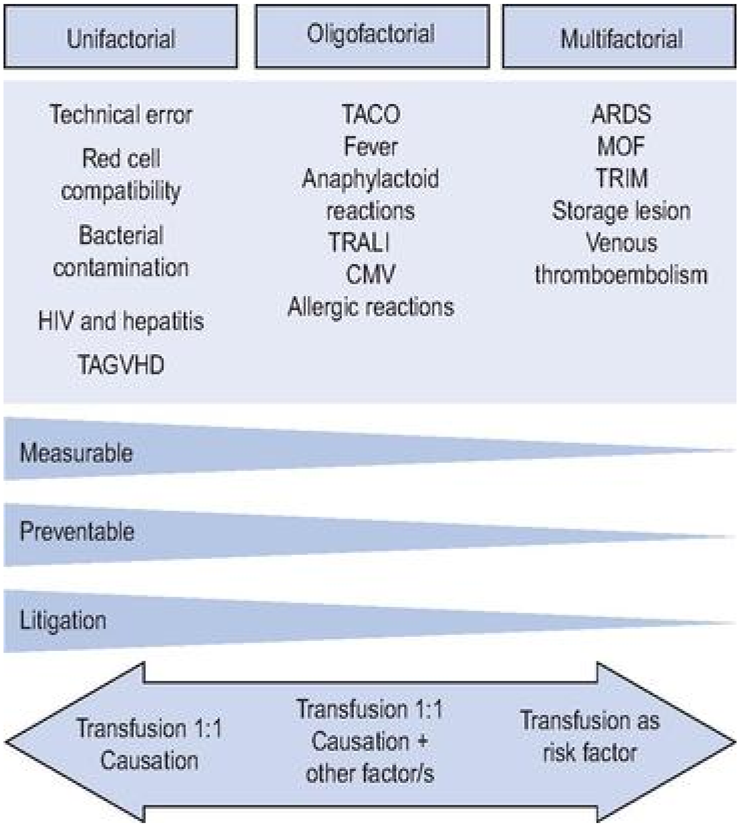
Recombinant activated factor VII (rFVIIa) was developed for the management of haemophilic patients with coagulation factor inhibitors; rFVIIa has been used ‘off label’ for controlling haemorrhage in the non-haemophilic setting. [32-34] Patients with uncontrolled critical bleeding and coagulopathy, despite large transfusions and surgical intervention, have significant mortality rates and rFVIIa in these clinical situations has been administered as salvage therapy. Whilst there are a number of case reports and series reporting on the use of rFVIIa in critical life-threatening haemorrhage, controlled studies have not demonstrated evidence for efficacy, and concern exists regarding thrombotic complications. Its routine use is not recommended. [35]

Potential Adverse Effects of Allogeneic Transfusion (Fig. 112.2)

Acute (<24 hours) Immunological Reactions

Acute Haemolytic Transfusion Reactions

The most severe acute haemolytic transfusion reactions are due to ABO incompatibility, have an identifiable cause and are avoidable, in contrast to delayed haemolytic reactions that are immune in nature and are difficult to prevent.



Unifactorial
Oligofactorial
Multifactorial
Technical error
Red cell compatibility
Bacterial contamination
HIV and hepatitis
TAGVHD
TACO
Fever
Anaphylactoid reactions
TRALI
CMV
Allergic reactions
ARDS
MOF
TRIM
Storage lesion
Venous thromboembolism
Measurable
Preventable
Litigation
Transfusion 1:1 Causation
Transfusion 1:1 Causation + other factor/s
Transfusion as risk factor

The diagram is organised into three vertical columns labelled unifactorial, oligofactorial, T A C O, and multifactorial. The unifactorial column lists causes such as technical error, red cell compatibility, bacterial contamination, H I V and hepatitis, and T A G V H D. The oligofactorial column includes fever, anaphylactoid reactions, T R A L I, C M V, and allergic reactions. The multifactorial column lists A R D S, M O F, T R I M, storage lesion, and venous thromboembolism. Below these columns, three horizontal arrows depict trends across the categories, namely, measurability and preventability decrease from left to right, while the likelihood of litigation increases. At the bottom, a double-headed arrow indicates conceptual framing, with unifactorial labelled as transfusion one-to-one causation, oligofactorial as transfusion one-to-one causation plus other factors, and multifactorial as transfusion as a risk factor.

FIG. 112.2 Algorithm for analysis of the possibility of a transfusion reaction. *ARDS* , adult respiratory distress syndrome; *CMV* , cytomegalovirus; *HIV* , human immunodeficiency virus; *MOF* , multiorgan failure; *TACO* , transfusion-associated circulatory overload; *TAGVHD* , transfusion-associated graft-versus-host disease; *TRALI* , transfusion-related acute lung injury; *TRIM* , transfusion-induced immunomodulation.

Initial Symptoms and Signs

The classic symptoms and signs of an acute haemolytic transfusion reaction, typical of ABO incompatibility, include apprehension, flushing, pain (e.g. at the infusion site, headache, chest, lumbosacral and abdominal), nausea, vomiting, rigours, hypotension and circulatory collapse. It is important that an acute haemolytic reaction is promptly recognised so that the transfusion can be ceased and management instituted to prevent complications.

Renal impairment may complicate a haemolytic transfusion reaction and its prevention or the appropriate management of established renal failure is important. If circulating volume and urinary output are rapidly restored, established renal failure is unlikely to occur. Death from acute renal failure directly caused by an incompatible blood transfusion is preventable unless there are other poor prognostic factors. A severe haemolytic transfusion reaction may be suspected from the development of jaundice, hemoglobinuria and anaemia.

Allergic and Anaphylactoid Reactions

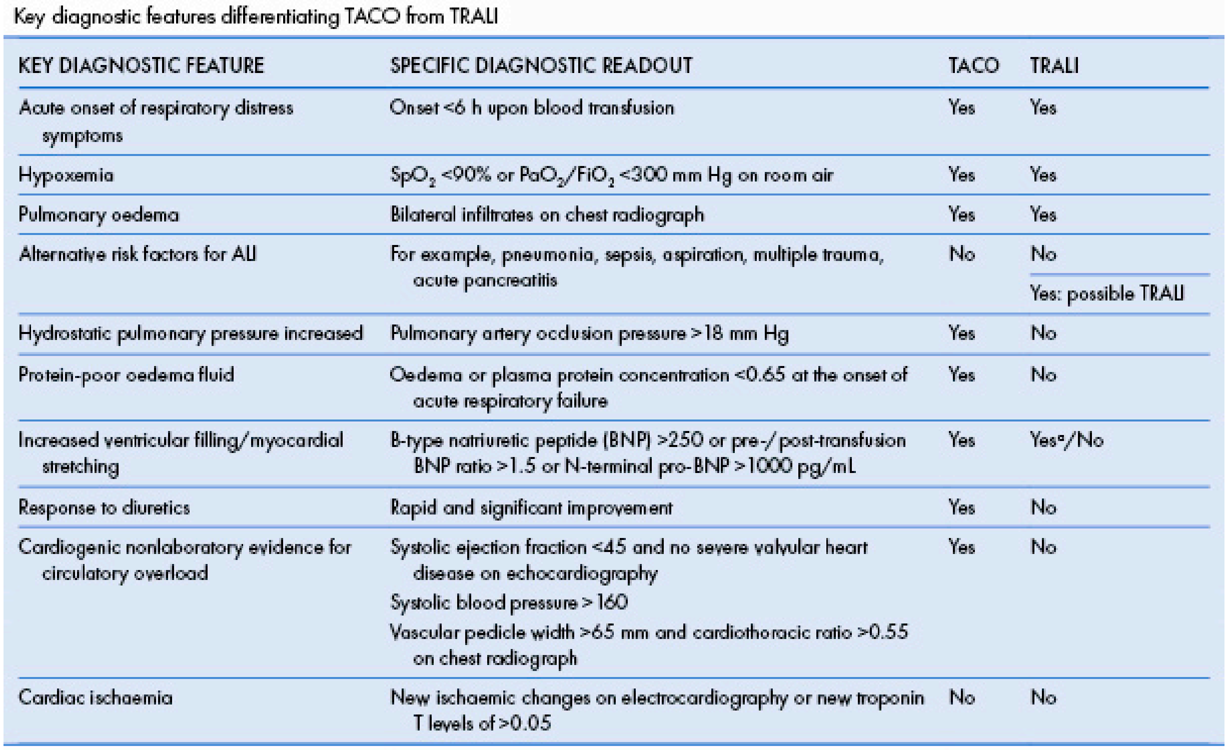
The clinical severity of allergic reactions to blood components ranges from minor urticarial reactions or flushing through to fulminant cardiorespiratory collapse and death. Some of these reactions are true anaphylaxis, but in others, the mechanisms have been less clear and the term ‘anaphylactoid’ has been used.

Potential causes for allergic reactions include IgA-deficient patients who have anti-IgA antibodies, plasma proteins in the transfused product or transfusing an allergen to a sensitised patient. If a patient has a significant allergic reaction to transfusion, consultation with a haematologist before administering additional blood components is recommended.

Transfusion-Related Acute Lung Injury

TRALI is a serious complication of blood transfusion and the leading cause of transfusion-related mortality in the United States.[36] The pulmonary complications of TRALI and Transfusion-Associated Circulatory Overload (TACO) were the leading causes of transfusion-related mortality and morbidity reported to the Serious Hazards of Transfusion haemovigilance programme from 2010 to 2020.[37] TRALI is characterised by new acute lung injury with onset of symptoms or signs within 6 hours of completion of transfusion of one or more plasma-containing blood products, with various clinical definitions proposed (Table 112.1).[38]

Table 112.1



Key diagnostic features differentiating TACO from TRALI

KEY DIAGNOSTIC FEATURE	SPECIFIC DIAGNOSTIC READOUT	TACO	TRALI
Acute onset of respiratory distress symptoms	Onset <6 h upon blood transfusion	Yes	Yes
Hypoxemia	SpO_2 <90% or PaO_2/FiO_2 <300 mm Hg on room air	Yes	Yes
Pulmonary oedema	Bilateral infiltrates on chest radiograph	Yes	Yes
Alternative risk factors for ALI	For example, pneumonia, sepsis, aspiration, multiple trauma, acute pancreatitis	No	No Yes: possible TRALI
Hydrostatic pulmonary pressure increased	Pulmonary artery occlusion pressure >18 mm Hg	Yes	No
Protein-poor oedema fluid	Oedema or plasma protein concentration <0.65 at the onset of acute respiratory failure	Yes	No
Increased ventricular filling/myocardial stretching	B-type natriuretic peptide (BNP) >250 or pre-/post-transfusion BNP ratio >1.5 or N-terminal pro-BNP >1000 pg/mL	Yes	Yes[a]/No
Response to diuretics	Rapid and significant improvement	Yes	No
Cardiogenic nonlaboratory evidence for circulatory overload	Systolic ejection fraction <45 and no severe valvular heart disease on echocardiography Systolic blood pressure >160 Vascular pedicle width >65 mm and cardiothoracic ratio >0.55 on chest radiograph	Yes	No
Cardiac ischaemia	New ischaemic changes on electrocardiography or new troponin T levels of >0.05	No	No

[a] In transfused critically ill patients.

Reproduced from Semple JW, Rebetz J and Kapur R. Transfusion-associated circulatory overload and transfusion-related acute lung injury. Blood 2019;133:1840–1853.

The underlying pathophysiology of 'classic' TRALI is incompletely understood, however, a 'two-hit' hypothesis has been proposed in which patients may be 'primed' by shock, sepsis or extracorporeal circulation, making them more susceptible to acute lung injury from blood transfusion. [37] The 'second hit' may be due to anti-leukocyte antibodies (usually anti-HLA class I or class II or anti-HNA antibodies) or other factors present in the transfused product.

As anti-leukocyte antibodies occur typically in plasma from multiparous females, male-donor-only fresh frozen plasma is now provided by most blood services to mitigate the risk of TRALI, and the universal use of male-donor only fresh frozen plasma has been associated with a reduction in TRALI reported to haemovigilance services. [39]

It is important for clinicians to recognise TRALI and to report suspected cases to hospital transfusion services, as this allows the specialised testing to confirm the diagnosis and also has implications for the future use of other blood components collected from the blood donor.

Febrile Non-Haemolytic Transfusion Reactions (FNHTRs)

Mild febrile reactions are not usually a matter of concern. The majority of febrile reactions are now considered to be an immunological reaction against one or more of the transfused cellular or plasma components, usually leucocytes.

Acute (<24 Hours) Non-Immunological Reactions

Transfusion-Associated Circulatory Overload

Transfusion-associated circulatory overload (TACO) is a common transfusion reaction and is a leading cause of transfusion-related mortality and morbidity.[37] This may be confidently established in some cases, but in others, there may be contributing factors, such as pulmonary capillary leak syndromes. Indeed, when there is no identifiable cause for dyspnoea and a definitive transfusion-associated cause of dyspnoea cannot be identified, but suspected, the term transfusion-associated dyspnoea (TAD) is used.

Bacterial Contamination

Bacterial contamination of stored blood is a recognised potential cause of fulminant endotoxic shock. Although a rare complication, continuing reports of its occurrence, especially in relation to platelet concentrate transfusion, have increased awareness.[40],[41] The clinical features of transfusion-related bacterial sepsis in the non-anaesthetised patient include rigours, fever, tachycardia and vascular collapse, with prominent nausea, vomiting and diarrhoea. Anaesthetised patients may have a delayed onset of symptoms (fever, tachycardia, hypotension and cyanosis), followed by DIC, renal failure and sometimes acute lung injury. The requirement to store platelet concentrates at room temperature increases the risks of bacterial contamination. Pre-release bacterial testing has been implemented in many blood services to reduce the risk.

Immunological Delayed (>24 Hours) Transfusion Reactions

Delayed Haemolytic Transfusion Reaction

Delayed haemolytic transfusion reactions are haemolytic transfusion reactions that occur more than 24 hours after transfusion and are usually due to an amnestic response to a donor red cell antigen to which the recipient has been previously exposed (e.g. through prior transfusion or pregnancy). They are usually identified when the patient develops signs or symptoms of haemolysis. The haemolysis is usually extravascular, so renal failure and DIC are not usually a feature.

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft versus host disease (TAGVHD) is a rare, but often fatal complication of blood transfusion. It occurs following a blood transfusion owing to the infusion of donor-viable T-lymphocytes engrafting and proliferating in the recipient, with consequent immunological reaction against the host tissues of the recipient. [42] It is most commonly observed in immunocompromised patients but may also be seen in recipients of directed blood donation from first-degree relatives, and occasionally where donor and recipient are not related, owing to homozygosity for human leucocyte antigen haplotypes for which the recipient is heterozygous. The syndrome usually occurs 3–30 days post-allogeneic transfusion with fever, liver function test abnormalities, profuse watery diarrhoea, erythematous skin rash and progressive pancytopenia. Gamma irradiation of blood products is currently the standard of care for the prevention of TAGVHD. [43]

Post-Transfusion Purpura (PTP)

Post-transfusion purpura is a rare transfusion reaction characterised by marked thrombocytopaenia 7-10 days following blood product transfusion.

Non-Immunological Delayed (>24 Hours) Transfusion Reactions

Transfusion-Transmitted Infections

Hepatitis

Post-transfusion hepatitis is a potential complication of allogeneic transfusion; donor selection, serological and nucleic acid tests ensure exclusion of infective donors. Hepatitis B and C are now almost totally preventable transfusion-transmitted infections.

Human Immunodeficiency Virus

Donor selection, antibody screening and nucleic acid testing of blood donors have almost eliminated transfusion-associated human immunodeficiency virus (HIV) infection.

Other Transfusion-Transmissible Infections

There is a range of emerging infectious diseases (e.g. dengue virus, West Nile Virus, Zika virus) that have the potential to be transmitted by blood transfusion. [44] Due to a range of factors (e.g. climate change, population growth and globalisation), the frequency of outbreaks of emergency infectious diseases is increasing. The reader is referred to reviews for further information regarding these potential transfusion-transmitted infections and the approach of blood services to mitigate these risks. [45-47]

Critical Bleeding and Massive Blood Transfusion

For the purpose of this discussion, critical bleeding refers to a major haemorrhage that is life threatening and is likely to result in massive transfusion (MT). Major haemorrhage can occur in a number of clinical situations and often requires a large volume transfusion of blood components and products. Although patients receiving MT represent only a small percentage of all transfused patients, they account for a significant percentage of blood components issued. Major haemorrhage and subsequent MT present clinical and logistic challenges to healthcare providers and transfusion services and are associated with significant morbidity and mortality. Major haemorrhage has traditionally been defined as the loss of more than one blood volume or requirement for transfusion of ≥10 red cell units in 24 hours.[16, 48] There is, however, no accepted consensus of what exactly defines an MT and the retrospective nature of the ≥10 red cell units in 24 hours definition limits its clinical utility,[49] More recently it has been suggested that more dynamic measures of MT be utilised that capture transfusion of all blood components (not just red cells) in a shorter timeframe.[50] These definitions potentially mimic the evolution of the major haemorrhage protocol (MHP) that aims to rapidly and simultaneously deliver blood products to the critically bleeding patient with an emphasis on rapid identification and control of haemorrhage. The Australian Government National Blood Authority has recently published an updated patient management guideline for adults with critical bleeding. Contemporary guidelines now no longer focus solely on the management of massive blood transfusion but emphasise the importance of the management of critical bleeding. The MHP includes a multidisciplinary team approach to the rapid identification and control of haemorrhage, timely delivery of blood components, and correction of coagulopathy and normalisation of physiological parameters.

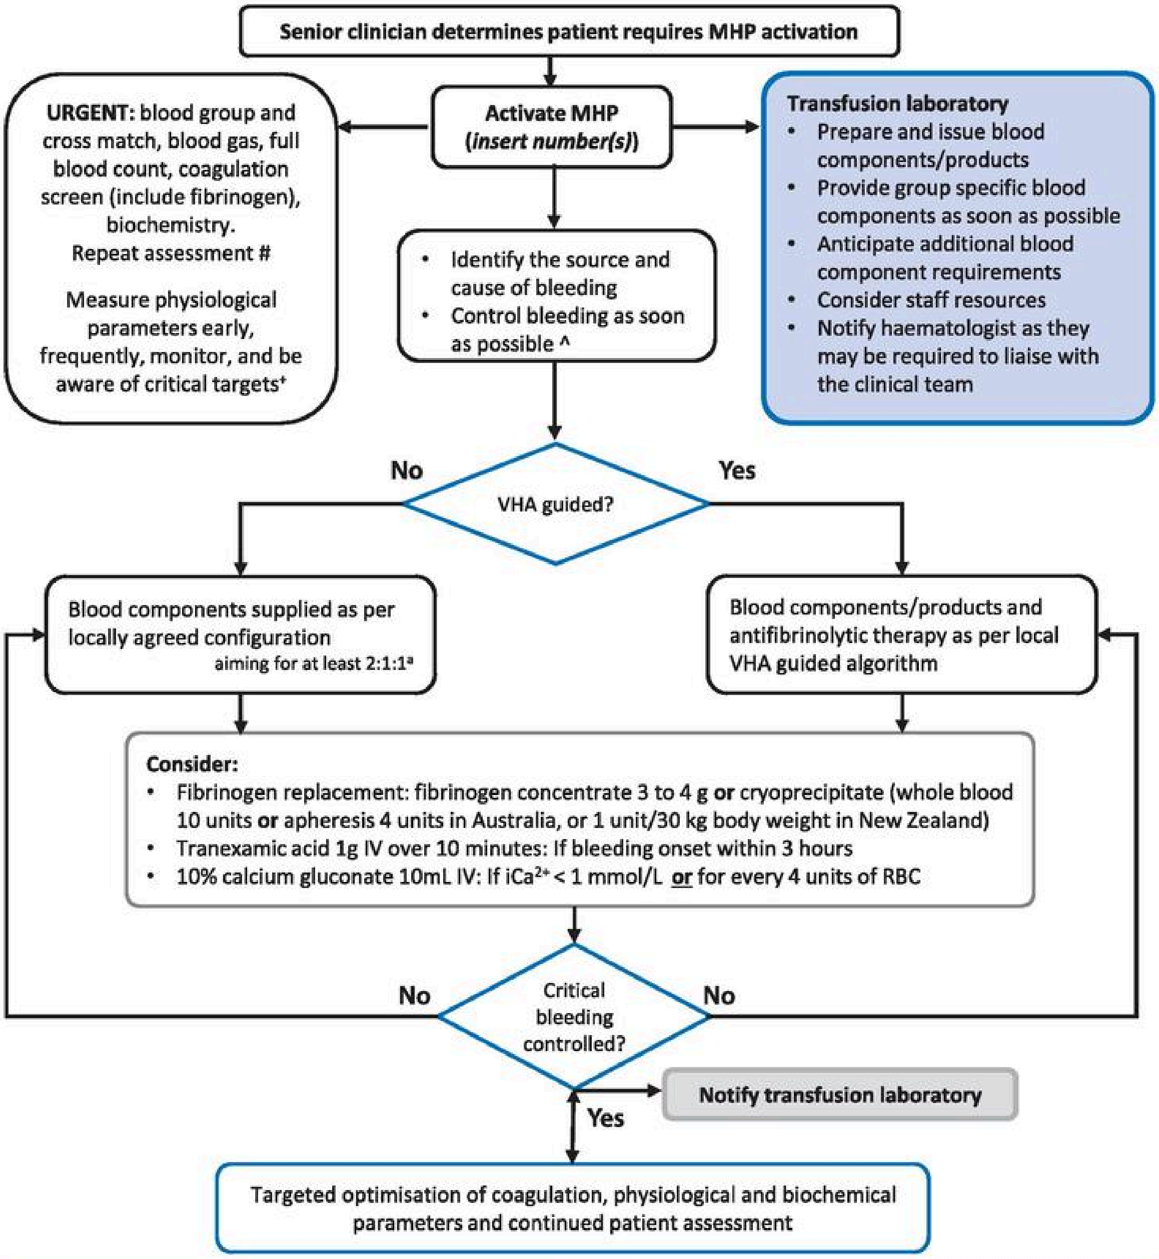
It is suggested that institutions develop an MHP to guide the initial response to critical bleeding that includes advice regarding the dose, timing and ratio of blood component therapy.[16] The MHP should also include advice regarding their activation, emphasise the importance of early control of bleeding, and facilitate communication and coordination between clinicians, laboratory staff and transfusion service providers. In addition to the activation of the MHP, there should be guidance to ensure the MHP is deactivated when haemorrhage is controlled to avoid inappropriate blood transfusion and limit potential wastage.

Few topics in critical bleeding management provoke as much debate and controversy as to what constitutes the 'ideal' MHP. Implementation of a robust MHP in concert with damage control resuscitation (DCR) and control of haemorrhage improves outcomes.[51-53] However, the blood product composition of the MHP remains one of the most hotly debated topics in resuscitation with widespread geographical and institutional variation in practice.[54], [55] Three strategies are commonly utilised – fixed ratio major haemorrhage protocol (FRMHP), VHA-guided MHP and Hybrid MHP. None is clearly superior, and each relies on robust institution-wide implementation dependent on local logistical considerations. In an FRMHP the predefined, balanced fixed ratio of blood and blood products is delivered empirically. There is sound evidence that the transfusion of large volumes of red blood cells (RBC) without concurrent coagulation factor replacement is associated with poor outcomes and implementation of an FRMHP can mitigate against this.[56], [74] In 2015 the PROPPR multicentre RCT reported improved very early survival in trauma patients receiving ratios approaching 1:1:1 (RBC:plasma:platelets), but this benefit was not evident at 30 days.[58] However, more patients receiving a 1:1:1 ratio achieved haemostasis and fewer died of haemorrhage. In PROPPR, blood product delivery was achieved rapidly, without significant wastage; however, this may not be possible in smaller, lower-volume institutions.[59] In Australia, pre-thawed plasma is not available in all institutions, a situation similar to that in the UK, with consequently few patients receiving 'optimal' ratios in a timely manner. A major advantage of a FRMHP is the rapid delivery of blood components independent of test results, however, even a 1:1:1 FRMHP delivers relatively dilute coagulation factors with limited effect on clotting.[60] Although the ideal ratio of RBC to plasma and platelets remains debated, the current evidence suggests that a ratio of at least 2:1:1 be utilised.[16]

Adult major haemorrhage protocol (MHP) *template**

***must be adapted to local institutional requirements and resources**

An MHP includes a multidisciplinary approach to haemorrhage control^, correction of coagulopathy and normalisation of patient physiological parameters *(insert key contact names and numbers)*



Senior clinician determines patient requires MHP activation

Activate MHP
(*insert number(s)*)

URGENT: blood group and cross match, blood gas, full blood count, coagulation screen (include fibrinogen), biochemistry.
Repeat assessment #

Measure physiological parameters early, frequently, monitor, and be aware of critical targets⁺

Transfusion laboratory
- Prepare and issue blood components/products
- Provide group specific blood components as soon as possible
- Anticipate additional blood component requirements
- Consider staff resources
- Notify haematologist as they may be required to liaise with the clinical team

- Identify the source and cause of bleeding
- Control bleeding as soon as possible ^

Blood components supplied as per locally agreed configuration
aiming for at least 2:1:1[a]

Blood components/products and antifibrinolytic therapy as per local VHA guided algorithm

Consider:
- Fibrinogen replacement: fibrinogen concentrate 3 to 4 g **or** cryoprecipitate (whole blood 10 units **or** apheresis 4 units in Australia, or 1 unit/30 kg body weight in New Zealand)
- Tranexamic acid 1g IV over 10 minutes: If bleeding onset within 3 hours
- 10% calcium gluconate 10mL IV: If $iCa^{2+} < 1$ mmol/L **or** for every 4 units of RBC

Notify transfusion laboratory

Targeted optimisation of coagulation, physiological and biochemical parameters and continued patient assessment

OPTIMISE	# REPEAT ASSESSMENT	⁺CRITICAL TARGETS	
- Oxygenation	(at least every 4 units of RBC):	- Temperature ≥ 35°C	- Platelets > 50 x 10^9/L
- Cardiac output	- Full blood count	- pH ≥ 7.2	- PT/APTT ≤ 1.5 x normal
- Tissue perfusion	- Coagulation screen	- Base excess ≥ -6mmol/L[b]	- INR ≤ 1.5
- Metabolic state	- Ionised calcium	- Lactate ≤ 4 mmol/L	- Fibrinogen ≥ 2.0 g/L
	- Blood gas	- iCa^{2+} ≥ 1.0 mmol/L	

a At least 1 unit FFP for every 2 units of RBC, and 1 adult dose PLT (equivalent to 4 donor units) for every 8 units of RBC.
b The normal range for base excess is -2 to +2. A base excess of ≥-6 refers to a base excess of -5, -4, -3 and so forth. A base excess of -7, -8, -9 and so on is associated with worsening prognosis.

The clinical flowchart is titled Adult Major Haemorrhage Protocol. It begins with the senior clinician determining whether the patient requires protocol activation. If activated, immediate steps include identifying the source and controlling bleeding, while the transfusion laboratory prepares and issues blood components. The left branch addresses urgent actions such as blood typing, coagulation screening, and physiological monitoring. The centre branch queries whether V H A guidance is used. If not, blood components are supplied per local configuration, aiming for at least a 2 to 1 ratio. If V H A guided, therapy follows a local algorithm. A section lists considerations including fibrinogen replacement, tranexamic acid administration, and calcium supplementation. The flow continues to assess if critical bleeding is controlled. If not, the transfusion laboratory is notified again. If yes, the process leads to targeted optimisation and patient reassessment. A bottom section outlines parameters to optimise, repeat assessment intervals, and critical targets such as temperature, base excess, and fibrinogen level.

Other considerations

^Haemorrhage control

- Early identification of cause of bleeding
- Control bleeding, using:
  - compression
  - packing
  - tourniquet
  - pelvic binder
- Surgical assessment:
  - early surgery or angiography to control bleeding

Suggested criteria for MHP activation

Clinical suspicion of critical bleeding **and** one or more of:

- Systolic blood pressure < 100 mmHg
- Heart rate > 100 bpm
- Positive focused assessment with sonography for trauma (FAST)
- Estimated blood loss > 1L
- Pallor

Resuscitation

- Institute active warming, avoid hypothermia
- Warm RBC through an approved blood warming device if available
- Prioritise blood components over crystalloids
- Consider permissive hypotension (systolic BP: 70 to 100 mmHg)

Special clinical situations

Direct oral anticoagulants

- Refer to haematologist

Warfarin reversal:

- Refer to warfarin reversal guidelines

Obstetric haemorrhage:

- Consider additional fibrinogen replacement

Severe traumatic brain injury:

- Permissive hypotension relatively contraindicated

Older adults:

- Hypotension and tachycardia may be late observations
- Caution with permissive hypotension

Suggested key contacts (*modify locally*)

- Blood bank/transfusion laboratory
- Anaesthetist
- Surgeon
- Haematologist
- Interventional radiology

Acronyms

APTT: activated partial thromboplastin time, **BP**: blood pressure, **bpm**: beats per minute, **iCa^{2+}**: ionised calcium, **FFP**: fresh frozen plasma, **INR**: international normalised ratio, **IU**: international unit, **IV**: intravenous, **MHP**: major haemorrhage protocol, **mmHg**: millimetres of mercury, **mmol/L**: millimoles per litre, **PLT**: platelets, **PT**: prothrombin time, **RBC**: red blood cells, **VHA**: viscoelastic haemostatic assays

Notes:

- This template was developed using the recommendations and good practice statements in the *Patient blood management guideline for adults with critical bleeding*. Recommendations in the guideline were based on the results of multiple systematic reviews. Good practice statements were developed based on indirect evidence and expert consensus. For further details see the full guideline.
- The content in this MHP is a guide only and must be adapted to local institutional requirements and resources. Health professionals should use clinical judgement and consider the clinical circumstances and patient preferences, to determine the appropriateness of this template for an individual patient.

The reference panel is titled Other considerations related to the adult major haemorrhage protocol. The top left panel outlines haemorrhage control methods, including early identification, compression, tourniquet, pelvic binder, and surgical control via surgery or angiography. The top right panel lists criteria for M H P activation, including systolic blood pressure less than 100 millimetres of mercury, heart rate above 100 beats per minute, positive trauma ultrasound, estimated blood loss over 1 litre, and pallor. The resuscitation section advises active warming, use of warm red blood cells through an approved warming device, prioritisation of blood over crystalloids, and permissive hypotension. The special clinical situations section addresses management with anticoagulants, warfarin reversal, obstetric haemorrhage, severe traumatic brain injury, and considerations for older adults. The key contacts panel suggests roles to involve, such as blood bank, anaesthetist, surgeon, haematologist, and interventional radiologist. The bottom panel defines medical acronyms, including A P T T, B P, B P M, I C a 2 plus, F F P, I N R, I U, I V, M H P, M M H G, millimoles per litter, P L T, P T, R B C, and V H A.

Failure of haemostasis is common in critically bleeding patients and is complex and multifactorial in pathogenesis. The underlying pathological process driving the requirement for MT can itself cause haemostatic failure that is then compounded by acidosis, hypothermia and dilution. In the setting of MT abnormal conventional coagulation tests (CCT) are associated with adverse outcomes but correlate poorly with clinical evidence of haemostatic failure and are ineffective in defining the various components of the clotting cascade contributing to coagulopathy. In addition, delay to result in availability often renders the results of limited use in active haemorrhage. Rapid identification of the characteristic coagulation disturbances associated with coagulopathy and its contribution to ongoing haemorrhage could facilitate interventions that reduce blood loss, limit blood product transfusion and ultimately reduce mortality. An alternative strategy utilises viscoelastic testing to assess clot formation in fresh or citrated whole blood in real time. Viscoelastic haemostatic assays (VHA) have potential advantages over CCT in the management of patients with major haemorrhage in terms of detecting coagulopathy and guiding therapy. [61] The heterogeneous nature of critical bleeding possibly renders an FRMHP too simplistic to be universally applied to all patients and the coagulopathy associated with major haemorrhage is a complex entity that changes over the time course of resuscitation. VHA-guided algorithms might enable rapid identification and correction of specific coagulation abnormalities.

A number of observational studies (the majority in the cardiac surgical and trauma patient populations) have reported improved patient outcomes with the incorporation of VHA in the management of major haemorrhage. [62] However, these findings have not been replicated in well-designed RCTs. The most recent systematic review conditionally recommends the use of VHA to guide blood component transfusion in major haemorrhage. [63] Whilst evidence of a positive impact on mortality is currently equivocal, it is apparent that VHA can be used to rapidly and reliably identify coagulopathic bleeding patients. [63] To what extent abnormalities in the coagulation system detected by VHA can be used to guide coagulation therapy as part of an MHP remains to be elucidated.

A hybrid strategy, combining initial FRMHP with subsequent VHA testing potentially combines the best of both strategies. [64] In the initial resuscitation of exsanguinating haemorrhage a 1:1:1 FRMHP is instituted and, as haemorrhage control is achieved, transitioning to a VHA-guided product replacement strategy. Promising initial results in terms of blood product utilisation and mortality have been reported [65] However, the recently published iTACTIC trial did not demonstrate a statistically significant difference in patient outcomes between a VHA and SLT-augmented MHP. [66]

Regardless of what strategy is employed the utility of an MHP is not restricted to the delivery of blood products, maybe more importantly is the activation of a highly trained multidisciplinary team focused on rapid identification and control of haemorrhage.

The Role of Factor Concentrates in MHP

There is increasing interest regarding the incorporation of factor concentrates into the MHP. The use of a predominantly factor-based resuscitation strategy vs fixed ratio blood component strategy incites great debate. There are staunch proponents for each but no Level 1 evidence to support the routine incorporation of factor concentrates into the MHP. A number of observational studies in trauma, obstetrics and cardiac surgery have reported positive outcomes with a factor-based strategy but these have not been replicated in well-designed large-scale RCTs. [68-70] In the absence of high-quality evidence supporting a factor-based strategy it could be argued that ‘deconstructing’ blood components to factor concentrates is not warranted in the management of major haemorrhage. However, it could also be argued that an initial factor-based strategy should be utilised when the rapid availability of blood components is not feasible. This strategy could be in the austere medical environment or when rapid replacement of coagulation factors is required.

Fibrinogen Replacement in the MHP

Fibrinogen plays a critical role in maintaining effective haemostasis in major haemorrhage. Fibrinogen is usually the first factor to reach critically low levels and hypofibrinogenaemia is associated with increased morbidity and mortality. [71] It is postulated that early fibrinogen replacement may assist in haemorrhage control, improve coagulopathy, and reduce transfusion requirements with positive effects on patient outcomes. Recently published guidelines suggest fibrinogen replacement should occur in the presence of plasma fibrinogen levels <2 g/L or thromboelastometric signs of fibrinogen deficiency. [72] Fibrinogen can be replaced with cryoeprecipitate or FC, each having advantages and disadvantages. The use of cryoprecipitate or FC for fibrinogen replacement remains one of the most hotly debated topics in major haemorrhage resuscitation with no Level 1 evidence to support the use of one above the other. The recently published CRYOSTAT 2 trial surprisingly reported no improvement in outcomes in trauma patients receiving early empiric cryoprecipitate as part of an MHP potentially tempering enthusiasm for early fibrinogen replacement.[73] The National Blood Authority guidelines suggest fibrinogen replacement in the presence of hypofibrinogenaemia using either cryoprecipitate (10 units whole blood derived or 4 unit apheresis) or FC 3–4 g.[16]

Tranexamic Acid (TXA) in Major Haemorrhage

The antifibrinolytic agent TXA is widely accepted as a useful adjunct in the management of critical bleeding. Two large-scale multicentre RCTs in trauma patients and postpartum haemorrhage demonstrated improved survival with early administration of TXA.[74], [75] It would appear that the beneficial effects of TXA are restricted to its early use within 3 hours of major haemorrhage. The recently published PATCH Trauma trial demonstrated an improvement in mortality in patients with severe trauma, however, this did not translate to improved functional outcomes at 6 months. Despite these findings, it is recommended that TXA be administered to severely injured trauma patients within 3 hours of injury.[76]

Specific Hazards of Massive Blood Transfusion

Any patient receiving massive blood component therapy is likely to be seriously ill and have multiple problems. Many adverse effects must be considered in conjunction with the injuries and multiorgan dysfunction. It is not always possible to define the complications caused or aggravated by massive blood transfusion.

Citrate Toxicity

A patient responds to citrate infusion by the removal of citrate and the mobilisation of ionised calcium. Citrate is metabolised by the Krebs cycle in all nucleated cells, especially the liver. A marked elevation in the citrate concentration is seen with transfusion exceeding 500 mL in 5 minutes; the level rapidly falls when the infusion is slowed. Citrate metabolism is impaired by hypotension, hypovolaemia, hypothermia and liver disease. Toxicity may also be potentiated by alkalosis, hyperkalaemia, hypothermia and cardiac disease. The clinical significance of a minor depression of ionised calcium remains ill defined, and it is accepted that a warm, well-perfused adult patient with normal liver function can tolerate a unit of blood every 5 minutes without requiring calcium. The rate of transfusion is more significant than the total volume transfused. Common practice is to administer 10% calcium gluconate (1.0 gm calcium gluconate in 10 mL) intravenously following every five units of blood or fresh frozen plasma. Such a practice remains controversial as there is concern regarding calcium homeostasis and cell function in acutely ill patients.

Acid–Base and Electrolyte Disturbances

Acid–Base

Stored bank blood contains an appreciable acid load and is often used in a situation of pre-existing or continuing metabolic acidosis. The acidity of stored blood is mainly due to the citric acid of the anticoagulant and the lactic acid generated during storage. Their intermediary metabolites are rapidly metabolised with adequate tissue perfusion, resulting in metabolic alkalosis. Hence the routine use of sodium bicarbonate is unnecessary and is contraindicated. Alkali further shifts the oxygen dissociation curve to the left, provides a large additional sodium load and depresses the return of ionised calcium to normal following citrate infusion. Acid–base estimations should be performed and corrected in the context of the clinical situation. With continuing hypoperfusion, however, the metabolism of citrate and lactate will be depressed. In this situation, intravenous bicarbonate and calcium to correct acidosis and low ionised calcium may be considered.

Serum Potassium

It is unlikely that the high potassium levels in stored blood (which may increase by 0.5 mmol/L per day of refrigerated storage) have pathological effects in adults. However, hypokalaemia may be a problem 24 hours after transfusion as the transfused cells correct their electrolyte composition and potassium returns into the cells. Thus although initial acidosis and hyperkalaemia may be an immediate problem with massive blood transfusion, the net result of successful resuscitation is likely to be delayed hypokalaemia and alkalosis. With CPD (citrate–phosphate–dextrose) blood, the acid load and red cell storage lesion are less. Constant monitoring of the acid–base and electrolyte status is essential in such fluctuating clinical situations.

Serum Sodium

The sodium content of whole blood and fresh frozen plasma is higher than the normal blood level due to the sodium citrate. This should be remembered when large volumes of plasma are being infused into patients who have disordered salt and water handling (e.g. in renal, liver or cardiac disease).

Hypothermia

Blood warmed from 4 to 37°C requires 1255 kJ (300 kcal), the equivalent heat produced by 1 hour of muscular work, with an oxygen requirement of 62 L. Hypothermia impairs the metabolism of citrate and lactate, shifts the oxygen dissociation curve to the left, increases intracellular potassium release, impairs red cell deformability, delays drug metabolism, masks clinical signs, increases the incidence of arrhythmias, reduces cardiac output and impairs haemostatic function. Thus a thermostatically controlled blood-warming device should be routinely used when any transfusion episode requires the rapid infusion of more than two units of blood.

Hyperbilirubinemia

Jaundice is common following massive blood transfusion as a significant amount of transfused stored blood may not survive, resulting in varying degrees of hyperbilirubinaemia. During hypovolaemia and shock, liver function may be impaired, particularly in the presence of sepsis or MOF. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Thus although an increased load of bilirubin from destroyed transfused red cells may be conjugated, there may be delayed excretion leading to conjugated hyperbilirubinemia. This ‘paradoxical’ conjugated hyperbilirubinaemia may be misinterpreted, leading to unnecessary investigations. The effect of resorbing haematoma and the possibility of an occult haemolytic transfusion reaction should also be considered.

Basic Immunohematology

Red cell serology is a highly specialised area of knowledge and it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety. The following is a summary of core knowledge for the clinician.

Saline Agglutination

Safe red cell transfusion has revolved around this traditional serological technique. A saline suspension of red cells is mixed with serum and observed for agglutination. Saline agglutination is used for ABO blood grouping and is one of the techniques for compatibility testing of donor blood.

The Direct and Indirect Antiglobulin TestIn red cell serology, the antiglobulin test (Coombs test) is used to detect IgG immunoglobulins or complement components. The direct antiglobulin test (DAT) detects immunoglobulin or complement components present on the surface of the red cells circulating in the patient. The result is positive in autoimmune haemolytic anaemia and haemolytic disease of the newborn and during a haemolytic transfusion reaction. The indirect antiglobulin test (IAT) detects the presence of non-agglutinating antibodies in the patient’s plasma, usually the IgG type. Antibody screening for atypical antibodies and pre-transfusion compatibility testing are the main applications of the IAT.

Regular and Irregular (Atypical) Antibodies

The regular alloantibodies (isoagglutinins) of the ABO system are naturally occurring agglutinins present in all ABO types (except AB), depending on the ABO group. Group O people have anti-A and anti-B isoagglutinins; group A has anti-B; and Group B has anti-A. Group A cells are the cause of the most common and most dangerous ABO-incompatible haemolytic reactions. Atypical antibodies are not normally present in the plasma but may be found in some people as naturally occurring antibodies or as immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies more frequently react by saline agglutination and, although they may be stimulated by transfusion, are usually of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance and their recognition is the raison d'être for pre-transfusion compatibility testing and antenatal antibody screening. Most of the clinically significant immune atypical antibodies are detected by the IAT.

Blood group antigens vary widely in their frequency and immunogenicity. The D antigen of the Rhesus blood group system is common and highly immunogenic. Thus when a Rh-negative (i.e. D-negative) patient is exposed to D-positive blood there is a high likelihood of forming an anti-D antibody. It is for this reason that the D antigen is taken into account when providing blood for transfusion, in contrast to the numerous other red cell antigens that are less common or less immunogenic. Beyond the Rh (D), and sometimes the Kell (K) blood group antigens, it is not practical, or necessary, to take notice of other blood group antigens unless an atypical antibody is detected during antibody-screening procedures.

The Antibody Screen

On receipt of a blood sample by the transfusion service, the red cells are ABO and Rh D typed, and the serum is screened for atypical antibodies. This screen consists of testing the patient’s serum with group O screening cells. The screening panel consists of red cells obtained usually from two group O donors containing all common red cell antigens occurring with a frequency of greater than approximately 2% in the community. If an atypical antibody is detected on the antibody screen, further serological investigations are carried out to identify the specificity of the antibody. These investigations are time-consuming and, when possible, should be carried out electively.

The Crossmatch (Compatibility Test)

The crossmatch is the final compatibility test between the donor cells and the patient's serum. This test tends to be overemphasised, to the detriment of the antibody screen. With sophisticated knowledge of serology, the emphasis on the supply of compatible blood is now concentrated on the steps prior to the final compatibility crossmatch.

The Type and Screen System

As pre-compatibility testing has assumed a major role in the selection of blood for transfusion, there has been a rethinking of policies relating to the supply of blood for elective transfusions. Whenever elective surgery is planned for a patient who is likely to require a blood transfusion, the transfusion service must receive a clotted blood sample well before the anticipated time of surgery. The pre-compatibility testing should be carried out during routine working hours when facilities are geared for large workloads and enough staff is available to handle all contingencies.

The Provision of Blood in Emergencies

When quick clinical and laboratory decisions are made under conditions of stress it is frequently difficult for all involved personnel to appreciate the difficulties of others. The decision to give uncrossmatched, partially crossmatched, or to wait for crossmatched compatible blood is not easy, and certain basic serological considerations may clarify for the clinician some of the problems faced by the serologist. Depending upon the degree of urgency and the extent of previous knowledge about the patient's red cell serology, blood can be provided with varying degrees of safety. However, it should be emphasised that when a patient is exsanguinating and likely to die, the giving of ABO-compatible uncrossmatched blood, especially if the antibody screen is negative, is a safe and appropriate therapy.

Universal Donor Group O Blood

Group O blood under normal circumstances will be ABO compatible with all recipients. The transfusions should be given as red cell concentrates screened for high-titre A or B haemolysins and used only in extreme emergencies. If the recipient is of childbearing age, every attempt should be made to give Rh-D-negative blood until the patient's blood group is known. [77]

ABO-Group-Specific Blood

Transfusion of the blood of the correct ABO type circumvents the isoagglutinin problems alluded to above. Simple as this approach may seem, its safety is dependent on meticulous attention to grouping. Previous blood group information, such as a 'bracelet' group or 'unofficial' group written in the patient's records, may be incorrect and there may be considerable risk if blood is administered on the basis of this information.

Blood Product Modification

Leucodepletion

Pre-storage leucodepletion of red cell and platelet concentrates minimises the clinical consequence of transfusion of leucocytes in blood products. There is evidence that leucodepletion reduces the risk of febrile non-haemolytic transfusion reactions, prevents platelet refractoriness by reducing alloimmunisation to leucocyte antigens, reduces the incidence of HLA alloimmunisation in organ transplant candidates and reduces the risk of certain TTI, particularly CMV. [78-83] Pre-storage leucodepletion may have a role in prevention of transfusion-related immunomodulation and the quality and function of pre-storage leucodepleted red cell concentrates is better maintained on storage, ensuring better post-transfusion efficacy and survival. [84] Many blood services, including Australia and New Zealand, have introduced universal pre-storage leucodepletion.

Gamma Irradiation of Blood Components

Irradiation of blood components is indicated for recipients who are at high risk of TAGVHD. Definite indications include directed donations (from a relative), HLA-selected/matched platelet transfusions, granulocyte transfusions, intra-uterine and subsequent neonatal exchange transfusions, congenital immunodeficiency, stem cell transplant recipients, patients receiving particular immunosuppressive therapy, including nucleoside analogues and alemtuzumab among others.[85],[86] It should be noted that irradiation of red cells increases the efflux of intracellular potassium which accumulates in the supernatant, and therefore their shelf-life is reduced to reduce the risk of high potassium, depending on the age of the recipient (e.g. neonates vs. adults).

CMV-Seronegative Blood Components

CMV is a potentially transfusion-transmissible infection, as latent virus can persist in leucocytes in cellular components, and can cause severe disease in susceptible recipients, including neonates and immunosuppressed patients. The two approaches to the prevention of transfusion-transmitted CMV (TT-CMV) are the selection of units from seronegative donors and leucodepletion of blood components. However, neither of these approaches eliminates the risk.[87] There are various international guidelines for indications for CMV-seronegative units, with most recommending seronegative blood components for intra-uterine transfusion, premature neonates, neonates <28 days from expected due date, granulocyte transfusions, pregnant women (regardless of CMV status) and certain immunocompromised patients.[87] However, if CMV-seronegative blood products are required in an emergency, and none are available, leucodepleted units of unknown CMV status may be used to avoid unnecessary delay to transfusion.

IgA-Deficient Components

These are indicated for recipients who are severely IgA deficient with known anti-IgA antibodies and who experience severe allergic reactions to blood components.

Blood Storage Lesion

Blood is altered from the moment of collection and the ‘lesions’ of the collection – anticoagulation, separation, cooling, preservation and storage – compound and progressively increase until the date of expiry.[88] Storage results in quantitative and/or qualitative changes in blood components, which may reduce the immediate efficacy of a transfusion. In parallel with these storage changes is an accumulation of degenerate material (e.g. microaggregates, microparticles and procoagulant material), the release of vasoactive agents, cytokine generation and haemolysis.

A number of large randomised controlled trials have compared ‘fresher’ to ‘older’ red cell transfusion in heterogeneous patient populations including the critically ill.[89-91] No effect on patient mortality was observed. When considered together these trials demonstrate that the age of red cell transfusion (up to the expiry date) does not affect patient outcome.

Haemostatic failure

James Winearls, Zoe McQuilten and Charithani Bhagya Keragala

Normal Haemostasis

The haemostatic system is tightly controlled to initiate clot formation where and when required and in adequate, but not excessive, amounts. There has been a paradigm shift in our understanding of the haemostatic system from one of circulating clotting factors to a more complex process occurring on the surface of activated or damaged cells (Fig. 113.1). The detailed diagram presents the coagulation cascade, divided into intrinsic, extrinsic, and common pathways, followed by fibrinolysis. The intrinsic pathway begins with factor twelve activation by H M W K collagen, followed by kallikrein and prekallikrein, leading to activation of factors eleven, nine, and eight. Thrombin (two a) plays a role in activating eight. Inhibitory drugs such as milvexian, abelacimab, and xisomab are shown. The extrinsic pathway starts with tissue injury, releasing tissue factor, which activates factor seven to seven a. Both pathways converge at factor ten, which, along with factor five and calcium ions, forms the prothrombinase complex. This converts prothrombin two to thrombin two a, which then converts fibrinogen one to fibrin one a and activates factor thirteen to thirteen a, stabilising the clot. Medications, such as apixaban, rivaroxaban, dabigatran, and argatroban, are depicted as inhibitors of specific steps. The fibrinolysis section shows conversion of plasminogen to plasmin by tissue plasminogen activator (T P A), breaking down the fibrin clot. Inhibitors such as alpha 2 antiplasmin and P A I 1 are also labelled. Arrows indicate activation flow, and red T bars mark inhibition points.

FIG. 113.1 Model of Coagulation.

The triad of vascular constriction, platelet plugging, and fibrin clot formation provides the framework for haemostasis. Fibrinogen is the bulk protein of the coagulation system and fibrin is the end-product of a cascade of proteolytic activity, whereby precursor coagulation proteins are activated to become potent proteolytic enzymes that ultimately contribute to thrombin formation. Thrombin converts fibrinogen to fibrin-soluble monomers, which subsequently polymerise to form the fibrin clot, which is then stabilised by factor XIII. Thrombin generation in small amounts initially occurs in relationship to tissue-factor-bearing cells. This is then transferred to the activated platelet surface where amplification occurs. [2]

Following injury, vascular constriction reduces bleeding and allows time to initiate haemostasis. This is accentuated by vasoconstrictors released in association with platelet plug formation. Vascular endothelial cells play an active role in haemostasis by synthesising substances that act at the membrane surface and/or interact with platelets and the coagulation system (e.g. prostacyclin, antithrombin, plasminogen activator, von Willebrand factor [vWF], thrombomodulin, heparin cofactor II and nitric oxide). [3]

The coagulation system has been traditionally simplified to comprise the 'extrinsic' and 'intrinsic' pathways of coagulation, although the process is much more complex and interconnected. Coagulation is thought to be triggered predominantly via the extrinsic pathway in vivo, where damaged tissues expose tissue factor (TF), a membrane-bound protein present in cells surrounding the vascular bed. Factor (F) VII and VIIa then bind TF, activating FX. FXa interacts with the cofactor FVa to form prothrombinase complexes, which generate a small amount of thrombin on the cell surface. FIX is also activated by the TF/VIIa complex; it does not play a significant role in the initiation phase of coagulation but diffuses across to platelets in the vicinity that have adhered in proximity to the site of the TF-bearing cells. FIXa binds to a specific platelet surface receptor and interacts with cofactor FVIIIa, leading to activation of FX directly on the platelet surface, resulting in the amplification and propagation of coagulation.

VWF is a multimeric glycoprotein (GP) that mediates platelet adhesion to the exposed sub-endothelium and links the primary vascular/platelet phase to coagulation by being the carrier protein for FVIII. FVIII dissociates from VWF to form a complex on the activated platelet surface with FIXa (tenase complex) to activate FX to FXa. Platelets interact with VWF via GP Ib–IX–V complexes. This results in platelet deceleration along the sub-endothelium, allowing platelet receptors to bind collagen. Adhesion to collagen and subsequent platelet activation is critical in haemostasis and is facilitated by platelet GPVI and GPIa–IIa receptors. [4] GPIb–IX–V and

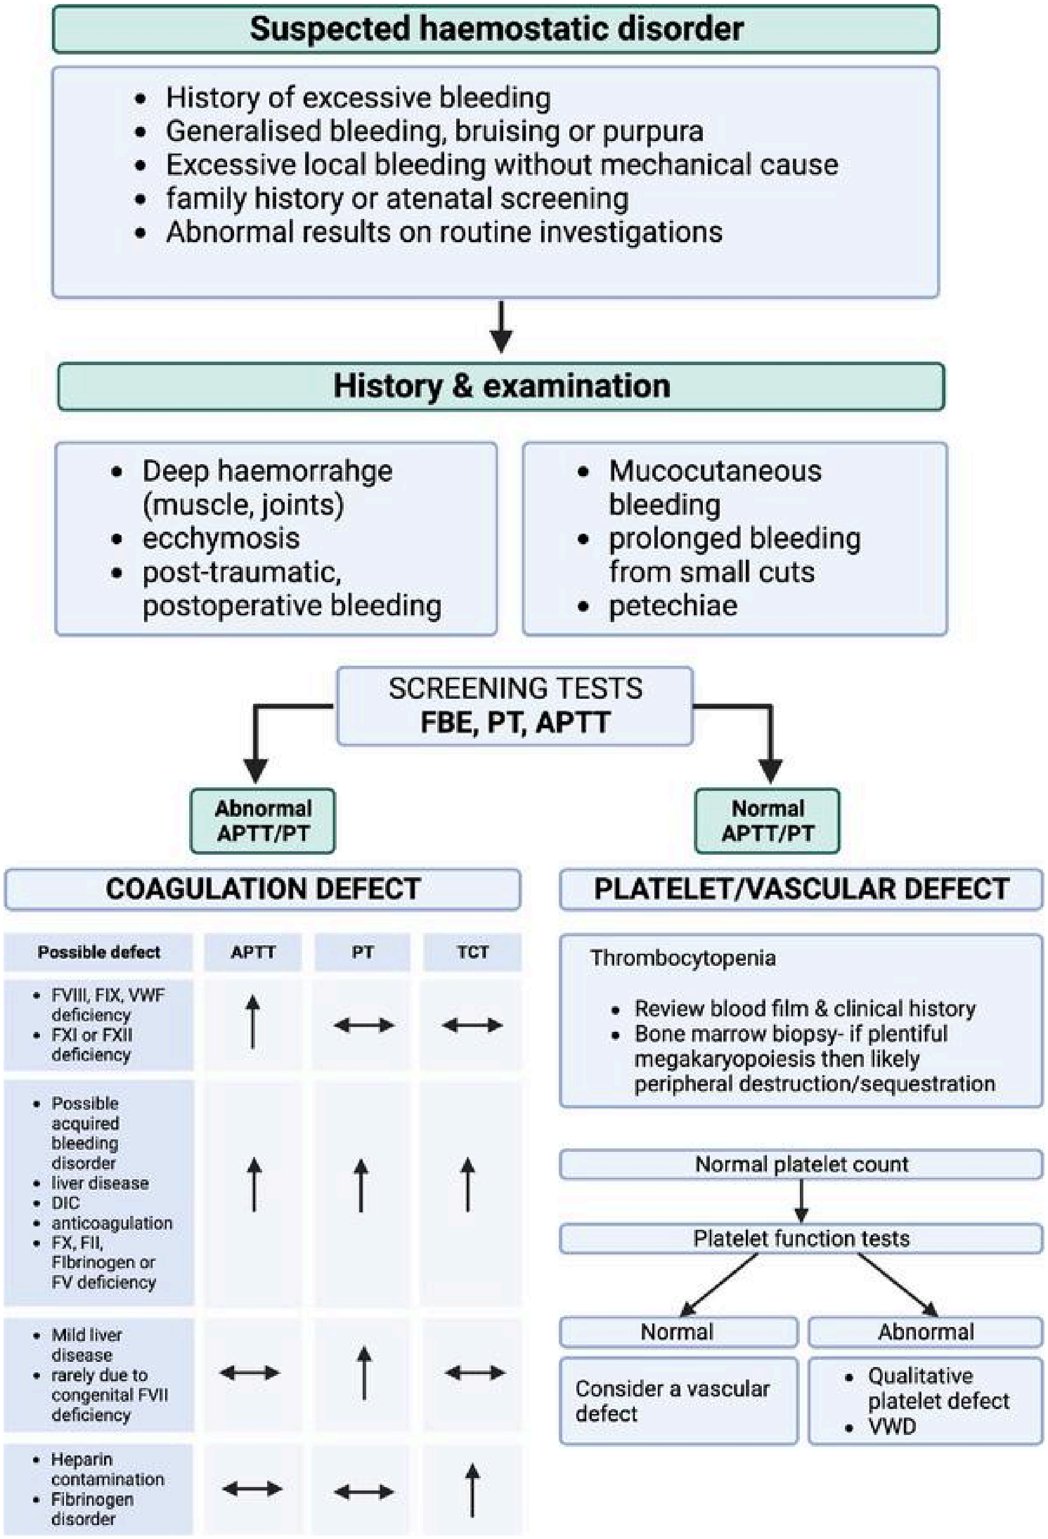
GPVI may work in concert to mediate platelet activation, culminating in stable platelet aggregation via the activation of GPIIb–IIIa.[5]

Platelet adhesion results in a platelet monolayer over the injured subendothelium, forming a procoagulant surface. Activation of the coagulation cascade results in local generation of thrombin, which binds to platelet protease-activated receptors (PARs), enhancing intracellular calcium mobilisation and platelet aggregation, resulting in production of a haemostatic plug and further facilitating coagulation. Further clot extension occurs due to platelet recruitment by platelet agonists, such as thrombin, adenosine 5-diphosphate (ADP) and thromboxane A_2, which are released directly from platelets. P-selectin is expressed during activation and plays a role in platelet-to-platelet and platelet-leucocyte interactions.

Parallel to and within the coagulation system are complex feedback mechanisms to guard against inappropriate and excessive activation.[6,7] Several inhibitory proteins, including antithrombin, thrombomodulin, proteins C and S, TF pathway inhibitors, together with the fibrinolytic system, are important in this regard. Thrombin itself acts as either a procoagulant or anticoagulant depending on the context to regulate the coagulation cascade at every step. Perturbations in this complex system can produce a wide range of clinical disorders from arterial or venous thrombosis to major bleeding.

Haemostatic Assessment

Clinical features may localise pathology to either coagulation factors or platelets (Fig. 113.2). Clinical history is important, especially previous bleeding, family history, medical co-morbidities and medications.



Suspected haemostatic disorder
History of excessive bleeding
Generalised bleeding, bruising or purpura
Excessive local bleeding without mechanical cause
family history or atenatal screening
Abnormal results on routine investigations
History & examination
Deep haemorrahge (muscle, joints)
ecchymosis
post-traumatic, postoperative bleeding
Mucocutaneous bleeding
prolonged bleeding from small cuts
petechiae
SCREENING TESTS
FBE, PT, APTT
Abnormal APTT/PT
Normal APTT/PT
COAGULATION DEFECT
PLATELET/VASCULAR DEFECT
Thrombocytopenia
Review blood film & clinical history
Bone marrow biopsy- if plentiful megakaryopoiesis then likely peripheral destruction/sequestration
Normal platelet count
Platelet function tests
Normal
Abnormal
Consider a vascular defect
Qualitative platelet defect
VWD

Possible defect	APTT	PT	TCT
• FVIII, FIX, VWF deficiency • FXI or FXII deficiency	↑	↔	↔
• Possible acquired bleeding disorder • liver disease • DIC • anticoagulation • FX, FII, FIbrinogen or FV deficiency	↑	↑	↑
• Mild liver disease • rarely due to congenital FVII deficiency	↔	↑	↔
• Heparin contamination • Fibrinogen disorder	↔	↔	↑

The diagram presents a structured diagnostic approach for suspected haemostatic disorders. It begins with indicators such as a history of excessive bleeding, generalised bruising or purpura, unexplained local bleeding, abnormal screening results, or positive family or antenatal screening. History and examination are categorised into two columns, including one for deep haemorrhage involving muscle, joints, ecchymosis, and postoperative bleeding, and the other for mucocutaneous bleeding, petechiae, and prolonged bleeding from minor cuts. Screening tests include F B E, P T, and A P T T. Based on results, the flow divides into two paths. An abnormal A P T T or P T leads to investigation of coagulation defects, with possible conditions including factor eight, nine, or von Willebrand factor deficiency, acquired inhibitors, liver disease, disseminated intravascular coagulation, and fibrinogen disorders. Arrows indicate which test results may be elevated. A normal A P T T and P T directs to evaluation of platelet or vascular defects, starting with assessment for thrombocytopenia via blood film and bone marrow biopsy. Platelet count guides further testing, distinguishing normal from abnormal function. Normal count may indicate vascular defect, abnormal function suggests qualitative platelet defects or von Willebrand disease.

FIG. 113.2 Assessment of Haemostasis.

Evaluation of the haemostatic system can be made using general and more specific and specialised laboratory assays. Viscoelastic haemostatic assays (VHA) are increasingly being used, particularly in the assessment of bleeding risk related to surgery, critical illness, and anticoagulant and antiplatelet therapy.

Evaluation of Platelets

A full blood count may reveal thrombocytopaenia. Whilst a low platelet count ($<50\times10^9$/L) can contribute to haemostatic failure, a normal platelet count does not exclude platelet dysfunction as a cause of bleeding. Platelet function tests can be used both for the diagnosis of platelet disorders and to monitor antiplatelet therapy but are not commonly indicated in the critical care setting outside haematology involvement.[8,9]

Specialised laboratory platelet function analysis can be used as a screening test for primary haemostatic defects. Normal results have a high negative predictive value, and the test is also sensitive to major bleeding disorders such as von Willebrand disease (vWD), Glanzmann thrombasthenia and aspirin use.[10] The development of whole blood multiple electrode platelet aggregometry (WBA) and light transmission aggregometry (LTA) to assess platelet function is promising. These devices are relatively simple to use with several assays available to assess various components of platelet function.[11] The principles are based on measuring the changes in electrical or light impedance caused by platelet aggregation in the presence of different agonists inducing platelet activation and aggregation. The rate of aggregation provides information on platelet function and response to antiplatelet agents. The use of these devices in assessing platelet response to aspirin, clopidogrel and GPIIb/IIIa has been published, with results correlating well with laboratory measures of platelet function.[12,13] In patients undergoing coronary artery stenting and neurointerventional radiology procedures the assessment of response to antiplatelet agents and subsequent risk stratification for thrombotic (antiplatelet non-responders) and haemorrhagic (antiplatelet hyper-responders) complications can be useful.[14-16]

Evaluation of Coagulation

A full blood count, prothrombin time (PT), activated partial thromboplastin time (APTT), fibrinogen level, D-dimer and thrombin time (TT) provide a broad screen for most clinically significant haemostatic disorders (Fig. 113.2).[17,18] Based on these results, further specific tests of haemostasis may be performed e.g., mixing studies, factor assays, platelet function tests and tests of fibrinolytic function.

Prothrombin Time

The PT is a test of the extrinsic coagulation system initially designed to monitor the response to warfarin. Prolongation may be caused by FVII deficiency, liver disease, vitamin K deficiency or oral anticoagulant therapy. The PT is also expressed as the international normalised ratio (INR), which allows comparison between laboratories.

Activated Partial Thromboplastin Time

The APTT is a test of the intrinsic coagulation system, and there may be significant variation in test sensitivity and specificity between laboratories due to the different reagents used for this assay. Prolongation of both APTT and PT may be due to deficiencies of factors X, V, prothrombin or fibrinogen. In a patient with a suspected systemic haemostatic defect and isolated prolonged APTT, the laboratory should first conduct a 1:1 ‘mixing study’ with normal plasma.

A prolonged APTT that fully corrects following a mixing study may represent:

- deficiency of FVIII, FIX or FXI, which can be further investigated with specific quantitative assays for these factors
- deficiency in the contact phase of coagulation; that is FXII and prekallikrein, which does not cause a bleeding phenotype.

A prolonged APTT that only partially corrects or fails to correct following a mixing study may be caused by:

- Heparin contamination of the sample (common reasons for prolonged APTT in critical care).
- Dabigatran.
- Acquired inhibitor of a coagulation factor (commonly FVIII, FIX) which is a haematological emergency as these patients can

exsanguinate rapidly and require urgent recombinant factor VIIa (rFVIIa) bypassing therapy to achieve haemostasis and immunosuppression to control the disease process.

- Presence of a lupus anticoagulant/inhibitor which paradoxically is associated with a pro-thrombotic phenotype rather than bleeding.

Thrombin Clotting Time

This is a test of the final conversion of fibrinogen to fibrin. Prolongation of thrombin clotting time (TCT) is due to hypofibrinogenaemia, dysfibrinogenaemia, UFH, direct thrombin inhibitors or the generation of fibrin-degradation products.

d-Dimer

The d-dimer assay measures cleavage fragments resulting from the proteolytic action of plasmin on cross-linked fibrin, so is specific for fibrinolysis and a marker of fibrin generation. Apart from venous thrombosis, raised d-dimer can be seen in, trauma, post-surgery, renal impairment, pregnancy, postpartum, sepsis and in disseminated intravascular coagulation (DIC) with hyperfibrinolysis.

Fibrinogen

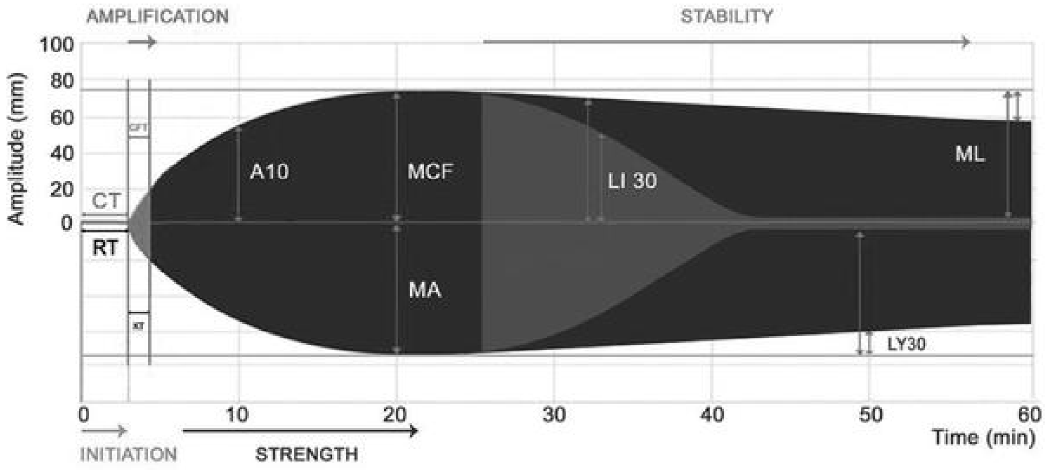
The two commonly used laboratory tests to quantify plasma fibrinogen levels are Clauss fibrinogen (FibC) and PT Derived Fibrinogen. [19] Fibrinogen is synthesised by the liver and can be markedly reduced in states of synthetic liver dysfunction. Fibrinogen is critical for accurate APTT and PT readings, hence significant deficiencies in fibrinogen should be corrected as a priority to ensure other coagulation parameters are interpretable.

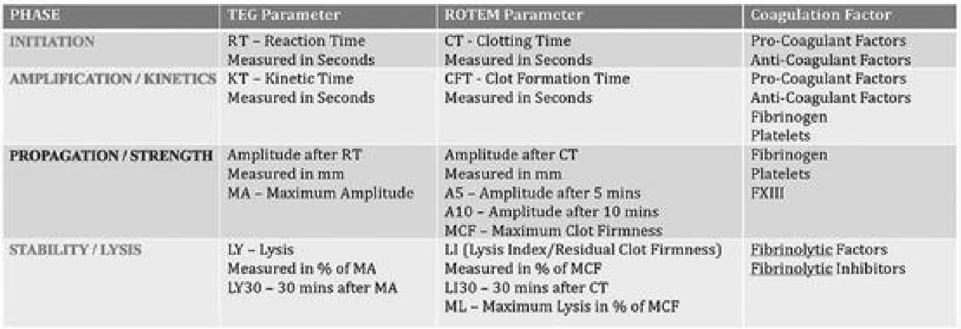
Viscoelastic Haemostatic Assays

Conventional coagulation assays (CCA) such as PT and APTT were developed for the detection of single-factor deficiencies and to monitor anticoagulation, however, may not provide a complete picture of haemostatic disturbance [20] and are poor predictors of bleeding or clotting. [17] The PT and APTT provide an indication of time to clot formation but not clot strength or stability. Delay in CCA result availability often renders the results of limited use in the time-critical environment of active haemorrhage. [21]

Viscoelastic haemostatic assays (VHA) may provide a more comprehensive picture of whole blood coagulation dynamics. [22] VHA assess cellular and plasmatic component interactions, providing dynamic information regarding clot formation, strength and fibrinolysis. [23-25] Result availability is rapid compared to CCA, potentially making them more suitable for guided administration of blood products in critical bleeding. [26]

Two VHA are widely and commercially available: TEG (Haemonetics, Braintree, MA, USA) and ROTEM (Werfen, USA). Neither device is superior and market share differs geographically. A comprehensive comparison between the technologies is beyond the scope of this chapter however, we will outline a few key features and recent advances. [27-29] In the first-generation VHA devices, a sample of whole blood is pipetted into a specially designed cup and pin system. The cup is then oscillated around the fixed pin (TEG 5000), or pin oscillated within a fixed cup (ROTEM Delta) and as a clot forms, impedance of cup or pin movement is detected. The viscoelastic properties of the clot over time are displayed graphically and numerically (Fig. 113.3). [30] Several assays utilising different activators and inhibitors are available to assess various components (fibrinolysis, platelets, fibrinogen, thrombin generation and heparin effects) of the coagulation system (Table 113.1). Due to differences in assays and device mechanics the results cannot be used interchangeably. [31, 32]





PHASE	TEG Parameter	ROTEM Parameter	Coagulation Factor
INITIATION	RT – Reaction Time Measured in Seconds	CT - Clotting Time Measured in Seconds	Pro-Coagulant Factors Anti-Coagulant Factors
AMPLIFICATION / KINETICS	KT – Kinetic Time Measured in Seconds	CFT - Clot Formation Time Measured in Seconds	Pro-Coagulant Factors Anti-Coagulant Factors Fibrinogen Platelets
PROPAGATION / STRENGTH	Amplitude after RT Measured in mm MA – Maximum Amplitude	Amplitude after CT Measured in mm A5 – Amplitude after 5 mins A10 – Amplitude after 10 mins MCF – Maximum Clot Firmness	Fibrinogen Platelets FXIII
STABILITY / LYSIS	LY – Lysis Measured in % of MA LY30 – 30 mins after MA	LI (Lysis Index/Residual Clot Firmness) Measured in % of MCF LI30 – 30 mins after CT ML – Maximum Lysis in % of MCF	Fibrinolytic Factors Fibrinolytic Inhibitors

The illustration presents a clot formation and stability profile using a combined thromboelastography and rotational thromboelastometry graph. The horizontal axis represents time in minutes from 0 to 60, and the vertical axis shows clot amplitude in millimetres up to 100. The process is divided into four phases, namely initiation, amplification or kinetics, propagation or strength, and stability or lysis. Key parameters labelled across the plot include R T, A 10, M A, M C F, L I 30, and M L. The clot grows in width from initiation through maximum clot firmness, then narrows in the stability phase. A table below outlines corresponding T E G and R O T E M parameters for each phase, including R T and C T for initiation, K and C F F for amplification, A and M A for propagation, and L Y 30 and M L for lysis.

FIG. 113.3 Viscoelastic Haemostatic Assay Trace.

Table 113.1

VHA assays

ASSAY	TEG ASSAYS (ACTIVATOR)	ROTEM ASSAYS (ACTIVATOR)	CLOTPRO ASSAYS (ACTIVATOR)	INTERPRETATION OF ASSAY
Contact activation pathway	Kaolin TEG (Kaolin)	INTEM (Ellagic acid)	IN-test (Ellagic acid)	Assesses the contact activation pathway (intrinsic pathway) partially measured by aPTT
Tissue factor (TF) activation pathway	–	EXTEM (Tissue factor)	EX-test (Tissue factor + Heparin blockade)	Assesses the tissue factor activated pathway (extrinsic pathway) partially measured by PT
Contact activation + TF pathway	RapidTEG (Tissue factor + kaolin)	–	–	Assesses both activation pathways
Heparinase	Kaolin TEG with lyoplilised heparinase	HEPTEM (Ellagic acid + lyophilised heparinase)	HI-test (Ellagic acid + heparin blockade)	Assesses the presence of systemic heparin via comparison with the Kaolin/INTEM/In-Test assay
Fibrinogen	TEG Functional Fibrinogen (Tissue factor + abciximab)	FIBTEM (Tissue factor + cytochalasin D)	FIB-test (Tissue factor + platelet blockade + heparin blockade)	Uses a platelet inhibitor to assess the relative contribution of fibrinogen to clot strength independent of platelets
FXa antagonists	–	–	RVV-test (Russel viper venom)	Detection of FXa antagonists
Thrombin antagonists	–	–	ECA-test (Ecarin + heparin blockade)	Detection of thrombin antagonists
Anti-fibrinolysis	–	–	TPA-test (Tissue factor + fibrinolysis activation + heparin blockade)	Assessment of anti-fibrinolysis (fibrinolytic resistance)

The TEG 6S and ROTEM Sigma are automated devices that have been developed based on first-generation technology and are widely available for clinical use. [29], [33] The relative ease of use, reduced operator variability and stability of the platforms have resulted in increased utilisation of both devices, especially in the point-of-care environment. [34] The TEG 6S is based on resonant frequency technology whereby changes in the resonant frequency of the sample indicate clot dynamics. Both systems use similar assays and utilise an automated cartridge system to control sample testing and provide similar results to the original devices. [35-38] The ClotPro system is a device that utilises similar cup and pin technology to the first-generation VHA devices. The blood sample is aspirated into the pipette tip containing the reagent and is automatically reconstituted. The ClotPro provides similar information to other VHA but with additional reagents providing information on fibrinolytic activity and the effects of DOACs on clot dynamics. Other devices using alternative methods are in development and/or available as research tools but are not widely used in clinical practice.[29, 30]

VHA are performed on whole blood and provide information on clot initiation, amplification, strength and stability allowing differentiation of the individual components contributing to clot kinetics to be assessed.[32] There are some advantages of VHA over CCA in certain circumstances, however, it must be recognised that VHA is still performed in artificial systems that cannot account for the effects of the endothelium and are unable to assess the contribution of vWF. Platelet function cannot be directly interrogated, and they are insensitive to the effects of antiplatelet agents.[39, 40] Both TEG and ROTEM have the additional capacity to assess for effects of antiplatelet agents.

VHA are mostly utilised in the context of major haemorrhage to identify causes of bleeding and guide blood product administration.[41] VHA have a higher sensitivity for the identification of the individual components of the haemostatic system and provide results more rapidly than CCA, potentially facilitating a patient-specific approach to correction of coagulopathy.[25, 26, 42] Treatment algorithms based on the results of VHA have been developed and incorporated into major haemorrhage protocols (MHP) for several critical bleeding scenarios.[43] In cardiac surgery, a number of RCTs and meta-analyses have suggested reduced blood product use with the use of VHA-directed transfusion algorithms and the use of VHA is endorsed by a number of professional societies.[44-46] In the trauma patient population, there has been widespread adoption of VHA into trauma MHPs in Europe and increasingly in Australia but less so in North America.[47-49] A single-centre RCT reported reduced mortality in patients treated with a TEG-guided transfusion algorithm.[50] However, these findings were not reproduced in the multicentre ITACTIC trial.[51] Despite the lack of a demonstrable reduction in mortality, VHA are increasingly being used as part of trauma MHP and their use is supported by a number of professional bodies[52, 53] (Fig. 113.4). The level of evidence in the obstetric patient population is low, with a recently published systematic review only identifying two low-quality RCTs. [54] There is slightly more evidence in patients with liver disease, with a recently published meta-analysis of 5 RCTs concluding that VHA-guided transfusion algorithms can reduce blood product transfusion requirements. The flowchart details the pathophysiology and clinical management of disseminated intravascular coagulation (D I C). It begins with modifying factors such as R E S function, blood flow, hepatic function, and the presence of inhibitors like A T three, platelets, and coagulation factors. Clinical features include shock, bleeding, and hypoxic organ damage. The normal haemostatic system transitions into D I C following an initiating event, such as trauma, infection, immune complexes, burns, fat embolism, obstetric shock, blood transfusions, haemolysis, envenomation, or malignancy. These lead to microvascular obstruction, factor depletion, and haemostatic factor depletion, contributing to further bleeding and organ damage. Central to the chart is the pathophysiology of D I C, linked to therapeutic strategies. Therapy is divided into cardiorespiratory support with intravenous fluids and red cells, and replacement therapy including fresh frozen plasma, cryoprecipitate, factor eight concentrates, platelets, fibrinogen concentrates, ultrafresh whole blood, or A T three concentrates. Heparin is noted as applicable generally in chronic D I C only. Arrows indicate feedback loops and interactions among bleeding, shock, depletion of haemostatic factors, and system reconstitution.

FIG. 113.4 VHA Guided Trauma Transfusion.

There is increasing interest in the use of VHA to assist management of critically ill patients with hypercoagulability and disordered fibrinolytic activity. Hypercoagulability can occur in several disease states, and it is postulated that the identification and risk stratification for thromboembolic events may be aided by VHA. The haemostatic disturbances associated with severe sepsis and DIC can range from hypocoagulability to hypercoagulability with or without disordered fibrinolytic activity. [56] Identifying where critically ill patients are in the spectrum of haemostatic disturbance at various time points during their illness could potentially allow therapy to reduce the risk of either bleeding or thrombotic complications. [57], [58]

Patients requiring extracorporeal support pose significant issues with bleeding and thrombosis. Anticoagulation is often required for the extracorporeal circuit, but this must be balanced against the risk of bleeding. There is increasing interest in the use of VHA to assess the complex haemostatic status of patients requiring extracorporeal support in an effort to balance the concurrent risks of bleeding and thrombosis and potentially guide anticoagulation. [59]

VHA can provide a more in-depth assessment of the complexities of the haemostatic system in critically ill patients. The dynamic nature of haemostatic disturbances in critically ill patients ranging from hypocoagulable to hypercoagulable can potentially be readily assessed using VHA. With the advent of new technologies and more refined assays, it is likely that their use in the critical care environment will continue to increase. [59] However, clinicians must be mindful to ensure that their use is evidence-based with appropriate clinical governance, including quality management systems.

Congenital Haemostatic Disorders

Congenital bleeding disorders are rare but should be suspected in the clinical setting with discrepant or unexpected major bleeding or with abnormal laboratory results (i.e. an isolated prolonged APTT). It is important to identify the defect so that specific replacement therapy can be administered, with dosage guided by regular coagulation factor level monitoring. Congenital bleeding disorders include haemophilia A (FVIII deficiency), haemophilia B (FIX deficiency) and vWD. Apart from specific factor concentrates, antifibrinolytics such as tranexamic acid are useful adjunctive therapy, with desmopressin also effective therapy in mild haemophilia A and certain types of vWD by stimulating endogenous release of FVIII and VWF.

Congenital platelet disorders are rare, the commonest severe disorder being Glanzmann thrombasthenia, which is a deficiency or dysfunction of GP IIb/IIIa. A history of repeated mucocutaneous bleeding with an abnormal aggregometry result is suggestive of such disorders. Platelet transfusions may be required for acute severe bleeds or in the peri-operative period; recombinant factor VIIa (rFVIIa) is important in cases of platelet transfusion refractoriness. Desmopressin (DDAVP) and antifibrinolytic therapy may also have a role. Congenital fibrinogen disorders are also rare conditions, caused by both quantitative and qualitative abnormalities, that may be associated with bleeding or thrombotic phenotypes. [60]

Acquired Platelet Disorders

Thrombocytopaenia is relatively common in critically ill patients and tends to occur more frequently in those with more severe organ dysfunction. [61] There are a multitude of causes of thrombocytopaenia in the critically ill and it can be difficult to ascertain the exact underlying cause (Box 113.1). The severity of the thrombocytopaenia can provide clues as to the potential underlying cause (Table 113.2). It is, however, extremely important to rule in or out those pathologies that require immediate therapy, such as heparin-induced thrombocytopaenia (HIT) and thrombotic thrombocytopaenic purpura (TTP). There is a lack of high-level evidence to guide the transfusion of platelets in the thrombocytopenic critically ill patient,[62] however, a number of guidelines are available to assist clinical decision making.[63] A platelet count of $>10\times10^{9}$/L is probably acceptable in terms of haemostasis for the majority of patients in the absence of active bleeding or invasive intervention. There is scant evidence to guide the transfusion of platelets in patients requiring interventions (e.g. central venous line (CVL) or percutaneous tracheostomy) but a platelet count of $>50\times10^{9}$/L would be considered sufficient for the majority of patients.[64] The recently published PACER trial demonstrated increased bleeding in patients with platelet count $<50\times10^{9}$/L not transfused platelets compared to those transfused prior to CVL insertion.[65] A larger trial is currently open to recruitment (the T4P trial), investigating various platelet transfusion thresholds for critically ill patients undergoing invasive procedures (ISRCTN79371664). In patients with active haemorrhage or concurrent haemostatic dysfunction, a higher platelet count may be required, especially for those with multi-trauma and those requiring neurosurgical intervention.[66]

Box 113.1

CAUSES OF THROMBOCYTOPAENIA

- Pseudothrombocytopaenia
- Sepsis
  - Bacterial, viral, fungal, parasitic
  - Human immunodeficiency virus (HIV)
  - Disseminated intravascular coagulation
- Major blood loss and haemodilution
- Mechanical fragmentation
  - Cardio-pulmonary bypass

  - Intraaortic balloon pump
  - Renal replacement therapy
  - Extracorporeal membrane oxygenation
  - Impella
- Immune-mediated disorder
  - Immune thrombocytopaenic purpura
  - Antiphospholipid syndrome
  - Post-transfusion purpura
- Microangiopathic haemolytic anaemia
  - Disseminated intravascular coagulation
  - Thrombotic thrombocytopaenic purpura
  - Haemolytic uremic syndrome
- Hypersplenism
- Other
  - Myelodysplastic syndrome
  - Malignancy
  - Chemotherapy
  - Drugs
- Hereditary thrombocytopaenia

Table 113.2

Severity of thrombocytopaenia

SEVERITY OF THROMBOCYTOPaENIA, × 10^9/L	**ASSOCIATED DISORDERS**
Mild to moderate, 75–150	Haemodilution, HIT, DIC, TMA
Moderate to severe, ~20–75	HIT, DIC, TMA
Very severe, <20	DITP, PTP, DIC (severe), PAT, TTP

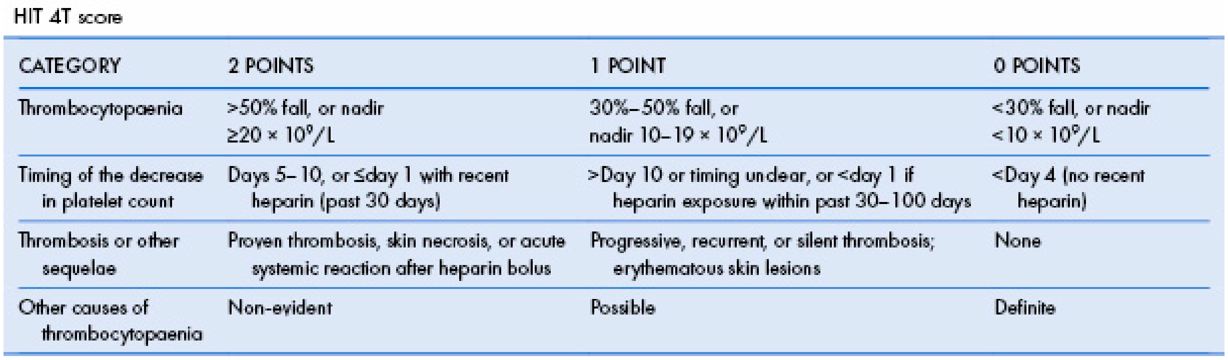
Drug-Induced Thrombocytopaenia

The clinical presentation of drug-induced thrombocytopaenia ranges from mild to life-threatening bleeding. Drugs with a predilection for inducing thrombocytopaenia include quinine, antituberculous drugs, heparin, thiazide diuretics, penicillins, sulfonamides, rifampicin, various anticonvulsants and vancomycin. The diagnosis of drug-induced thrombocytopaenia is particularly challenging in the critically ill, as patients can be exposed to multiple possible causative agents. Treatment involves discontinuation of the implicated drug/s, and the platelet count should begin to recover after 4 to 5 half-lives of the responsible drug or drug metabolites. [67]

Heparin-Induced Thrombocytopaenia

Heparin-induced thrombocytopaenia (HIT) is an important condition to promptly recognise as it can be potentially life-threatening. [68] It is caused by an immune reaction to heparin, typically after 7–10 days of heparin therapy, leading to platelet aggregation and thrombocytopaenia. The thrombocytopaenia seen in HIT usually does not fall below 20×10^9/L, and the platelet count can be normal. HIT is not associated with bleeding, but rather represents a pro-thrombotic state, manifesting as arterial or venous thrombosis. Medical staff must be vigilant to the possibility of HIT occurring, and to keep heparin therapy as brief as possible. The incidence is less with the use of low-molecular-weight heparin (LMWH). The clinical probability of HIT can be estimated based on four criteria used in the 4T score: timing and nadir of thrombocytopaenia, the presence of thrombosis, and the possibility of other causes accounting for thrombocytopaenia (Table 113.3) A strong clinical suspicion of HIT, based on the 4T score, should result in the immediate cessation of heparin, and the commencement of an alternate ‘non-heparin’ anticoagulant, such as danaparoid, fondaparinux, bivalirudin or argatroban, whilst awaiting laboratory results. [69]

Table 113.3



HIT 4T score

CATEGORY	2 POINTS	1 POINT	0 POINTS
Thrombocytopaenia	>50% fall, or nadir ≥20 × 10^9/L	30%–50% fall, or nadir 10–19 × 10^9/L	<30% fall, or nadir <10 × 10^9/L
Timing of the decrease in platelet count	Days 5–10, or ≤day 1 with recent heparin (past 30 days)	>Day 10 or timing unclear, or <day 1 if heparin exposure within past 30–100 days	<Day 4 (no recent heparin)
Thrombosis or other sequelae	Proven thrombosis, skin necrosis, or acute systemic reaction after heparin bolus	Progressive, recurrent, or silent thrombosis; erythematous skin lesions	None
Other causes of thrombocytopaenia	Non-evident	Possible	Definite

From Lo GK, et al., Evaluation of pretest clinical score (4 T's) for the diagnosis of heparin-induced thrombocytopenia in two clinical settings. *J Thromb Haemost* . 2006;4(4):759-765.

HIT can be challenging to diagnose in the critical care setting, with many potential causes of thrombocytopaenia in the same clinical scenario. Screening tests for HIT antibodies are available, but these also detect non-pathogenic antibodies, which can commonly occur in the setting of cardiac surgery, resulting in false positive results. Functional HIT assays, such as the serotonin release assay or whole blood aggregometry, which show platelet activation in the presence of heparin and patient serum/plasma, can confirm the diagnosis but are performed only in reference laboratories. [11]

Thrombotic Microangiopathies

Thrombotic microangiopathies (TMAs) are disease entities characterised by microvascular endothelial cell injury and the formation of platelet microthrombi. They are classically defined by thrombocytopaenia, microangiopathic haemolytic anaemia (MAHA) and variable organ involvement. Recent advances in understanding of the pathophysiology of the TMAs have enabled classification into three primary disorders:

- Thrombotic thrombocytopaenic purpura (TTP), which is triggered by deficiency of ADAMTS-13 (a disintegrin and metalloproteinase

with a thrombospondin type 1 motif, member 13), a metalloproteinase that cleaves pro-thrombotic large VWF multimers.
- Shiga toxin-producing *Escherichia coli* haemolytic-uraemic syndrome (STEC-HUS), more often seen in the paediatric setting and characterised by gastrointestinal involvement.
- Atypical haemolytic-uraemic syndrome (aHUS), which is driven by dysregulation and uncontrolled activation of the alternative complement pathway and is often characterised by renal impairment.

The three entities can be indistinguishable on clinical grounds, and any organ can be impacted by TMAs.[70] However, the lung is almost never involved in TTP, and severe acute renal failure at presentation is unusual in TTP. In fact, serum creatinine of >150–200 µmol/L and/or a platelet count >30 × 10^9/L makes TTP very unlikely.[71] Platelet counts can be normal or only mildly reduced in aHUS, and the greater the systemic organ involvement, the more likely the offending TMA is aHUS.

Laboratory testing is crucial in determining the precise TMA, with stool culture positivity for STEC definitive for STEC-HUS, and an ADAMTS-13 level of less than 5%–10% associated with TTP. Hence, aHUS remains a diagnosis of exclusion in the acute setting. Analysis of complement and genetic markers for aHUS are now available and are important for prognosis, but are not required for diagnosis of aHUS acutely.[72]

Timely diagnosis of TTP is essential, as this is a medical emergency with high morbidity and mortality if not treated promptly. The diagnosis is based on clinical features in combination with a low ADAMTS13 activity. However, the PLASMIC score can be used to estimate the likelihood of TTP, which may support the initiation of presumptive treatment with therapeutic plasma exchange whilst awaiting for ADAMTS13 activity levels if not immediately available. The PLASMIC score assigns values for clinical and laboratory features.[73]

It is important to determine the specific TMA, as these conditions have different management strategies. Plasma exchange, corticosteroids, rituximab and caplacizumab are the mainstay of management for TTP, whereas eculizumab (a monoclonal antibody directed against the complement component C5) is first-line therapy for aHUS. [74-76]

Clinicians should also be aware of secondary causes/triggers of TMA, including malignant hypertension, medications such as chemotherapeutic agents, clopidogrel, and calcineurin inhibitors, pregnancy, malignancy, organ transplantation and infections.

Idiopathic Thrombocytopaenic Purpura

Idiopathic thrombocytopaenic purpura (ITP) is an autoimmune disorder where autoantibodies (IgG) are directed against platelets, which are subsequently destroyed by the monocyte–macrophage system, predominantly in the spleen. ITP remains a diagnosis of exclusion. Corticosteroids are first-line therapy in acute episodes, particularly if the platelets are $<30 \times 10^{9}$/L or with uncontrolled bleeding. High-dose dexamethasone (40 mg/day for 4 days) is increasingly used and has demonstrated efficacy in this setting. [77] Intravenous immunoglobulin is indicated in ITP with major bleeding and/or not responding to corticosteroids and is particularly useful pre-operatively and in pregnancy. Platelet transfusions should be reserved for life-threatening bleeding and a platelet increment is more likely following a dose of intravenous immunoglobulin. Patients with refractory ITP are treated with thrombopoietin receptor agonists (romiplostim and eltrombopag), splenectomy or rituximab. [78]

Qualitative Platelet Defects

The most common cause of acquired platelet dysfunction seen in the critical care setting is the use of antiplatelet therapy. Other causes of platelet dysfunction include uraemia, cirrhosis, myeloproliferative disorders and exposure to extracorporeal circuits. Platelet dysfunction caused by extracorporeal circulation, especially cardio-pulmonary bypass, is associated with significant risk of bleeding. In the setting of CPB, bleeding risk is also impacted by other haemostatic disturbances, including dysfibrinogenaemia, fibrinolysis and complexity of surgery.

Haemostatic Failure Associated with Liver Disease

The majority of haemostatic proteins are synthesised in the liver, apart from FVIII and VWF. In chronic liver disease, a rebalanced haemostatic state is reached with a simultaneous reduction in both procoagulant factors and physiological anticoagulants (Protein C and S). [79] Bleeding and thrombosis risk is challenging to evaluate, with prohaemostatic changes (including reduced levels of natural anticoagulants and plasminogen) and antihaemostatic changes (thrombocytopaenia, platelet dysfunction, impaired synthesis of clotting factors and excessive fibrinolysis) co-existing. Abnormalities in coagulation tests do not necessarily correlate with increased bleeding risk and should not routinely trigger coagulation factor replacement in the absence of active bleeding. There is limited evidence to guide the use of prophylactic transfusion of fresh frozen plasma (FFP) or platelets in the periprocedural setting. Guidelines advise assessing individual patient bleeding risk in those undergoing invasive procedures prior to prophylactic transfusion of coagulation factors. [80] Coagulation factors can be replaced using FFP or prothrombin complex concentrate (PCC), each with its own pros and cons. FFP contains all the coagulation factors but significant volumes are required, placing the patient at risk of fluid overload and potentially exacerbating portal hypertension and thus aggravating bleeding. [81] PCC is an alternative, particularly in patients with fluid overload, however, should be used with care as it contains mostly procoagulant factors and may potentially increase risk of thrombotic complications. Four-factor PCC contains factors II, VII, IX and X, with a final overall coagulation factor concentration approximately 25 times higher than in normal plasma. [82] To prevent the spontaneous activation of these factors, PCC also contains heparin. PCC may also contain natural anticoagulation proteins, protein C and protein S, and these properties need to be taken into consideration when administering large doses of this product to an already bleeding patient. Haemostatic defects due to vitamin K deficiency, especially in patients with predominantly cholestatic liver disease, should be reversed with vitamin K. A restrictive RBC transfusion strategy in acute upper GIB is supported by RCT evidence and it would seem prudent to employ a similarly restrictive policy for the transfusion of coagulation factors and platelets.[83] Hypofibrinogenaemia, due to reduced synthesis, and dysfibrinogenaemia, caused by the failure of normal enzymatic removal of sialic acid from fibrinogen, are common in patients with liver impairment. In the setting of active haemorrhage, dedicated fibrinogen replacement using cryoprecipitate or fibrinogen concentrate may be required in addition to plasma. Patients with chronic liver disease may be at risk of fibrinolysis-related bleeding due to impaired hepatic metabolism of plasminogen activator. However, the routine use of high-dose TXA is not recommended for the management of upper gastrointestinal bleeding following the HALT-IT trial. This was a placebo-controlled RCT of 1g bolus followed by 3g IV infusion over 24 hours which failed to demonstrate the benefit from TXA on mortality or rebleeding in patients with acute UGIB, but did report a small increase in adverse events, specifically venous thrombosis and seizures.[84]

COVID-19 Haemostatic Disturbance

COVID-19 is associated with complex, multifactorial haemostatic abnormalities associated with thromboembolic complications.[85] COVID-19-associated coagulopathy (CAC) is an incompletely understood entity but involves the complex interplay between the virus itself, innate immune response, endothelium and the coagulation system resulting in a procoagulant state. CAC can result in micro and macrovascular thrombosis involving multiple organ systems and is associated with increased morbidity and mortality.[86] CAC is characterised by elevated D-dimer, CRP and fibrinogen levels. The haemostatic disturbances associated with COVID-19 prompted a number of studies investigating various anticoagulation strategies.[87], [88] In the non-critically ill hospitalised COVID-19 patient population, the use of therapeutic anticoagulation with heparin increased the probability of survival and reduced the requirement for organ support.[89] However, these findings were not observed in critically ill patient population and increased intensity anticoagulation above standard thromboprophylaxis therapy is not supported.[90-92] The RECOVERY and REMAP-CAP platform trial investigators did not demonstrate a reduction in composite of mortality or requirement for invasive organ support in those patients randomised to receive antiplatelet therapy.[93], [94] There is no evidence to support routine use of increased intensity of anticoagulation using unfractionated heparin (UFH), LMWH, DOACs or aspirin in critically ill patients with COVID-19.

Extracorporeal Support Therapy Haemostatic Disturbance

The haemostatic disturbances associated with extracorporeal support therapies are extremely complex and challenging to manage.[95] There are a number of cardio-respiratory support modalities and configurations available, including veno-arterial (VA) and veno-venous (VV) extracorporeal membrane oxygenation (ECMO), ventricular assist device (VAD) and Impella, which are all associated with differing degrees of haemostatic disturbance.[96] The majority of critically ill patients requiring extracorporeal support will have a degree of haemostatic failure due to the underlying disease process, severity of illness, organ failure, systemic inflammation and anticoagulant therapies in addition to the effects from exposure to an extracorporeal circuit.[97] Exposure to the artificial extracorporeal circuit, associated shear stress and non-pulsatile flow results in coagulation factor consumption and platelet dysfunction. The risk of haemorrhagic complications is exacerbated in particular by hypofibrinogenaemia, fibrinogen dysfunction, platelet dysfunction, reduced Factor VIII activity and acquired vWF deficiency. The presence of coagulopathy and diffuse microvascular bleeding should prompt an urgent assessment of extracorporeal circuit function. In addition to haemorrhagic complications, patients requiring extracorporeal support are at significant risk of thromboembolic complications. Contact activation of coagulation factors and platelets with an artificial circuit promotes a pro-thrombotic state and some degree of anticoagulation to maintain circuit patency is usually required. Balancing the competing risks of haemorrhage against thrombosis is extremely challenging and requires a multimodal and multidisciplinary approach to management. CCA may not provide comprehensive information on the haemostatic status of these patients and the combination of additional assays including ATIII, anti-Xa levels and VHA are often required.[98]

Disseminated Intravascular Coagulation

DIC is a pathophysiological process characterised by dysfunctional excessive activation of the haemostatic system leading to microvascular thrombosis with consumption of coagulation factors and platelets. Initially, adequate compensation results in defects being demonstrable only in the laboratory tests, but if the initiating disorder is severe the clinical syndrome of uncontrolled acute DIC can result in thrombosis, multi-organ failure and significant bleeding. Secondary hyperfibrinolysis can occur, which may accentuate the bleeding. Hypofibrinolysis is more common in sepsis-driven DIC, with resultant multi-organ microvascular thrombosis, whereas malignancy-driven DIC is more commonly associated with a hyperfibrinolytic phenotype.[99, 100]

Mechanisms that may inappropriately activate the haemostatic system leading to DIC include:

- Activation of the coagulation sequence by the release of tissue thromboplastins into the systemic circulation: following extensive tissue trauma, during surgery, malignancy and during acute intravascular haemolysis.
- Vessel wall endothelial injury causing platelet activation followed by activation of the haemostatic system: Gram-negative sepsis from endotoxin release, viral infections, extensive burns, prolonged hypotension, hypoxia or acidosis.
- Induction of platelet activation: septicaemia, antigen–antibody complexes.

Clinical Features

The clinical presentation of DIC varies, with patients showing thrombotic, haemorrhagic, or mixed manifestations in various organ systems. The major clinical problem of acute DIC is bleeding, manifesting as generalised bruising, or bleeding at venepuncture sites and surgical wounds. DIC may occur in association with a wide range of clinical disorders (Box 113.2).

Box 113.2

Conditions associated with DIC

- Infection
- Bacterial sepsis
- Viral haemorrhagic fevers
- Protozoal (malaria)
- Trauma
- Extensive tissue injury
- Head injury
- Fat embolism
- Malignancy
- Carcinoma
- Leukaemia (especially promyelocytic)
- Immunological disorders
- Transplantation rejection
- Incompatible haemolytic blood transfusion reactions
- Severe allergic reaction
- Drug reactions
- Extracorporeal circulations
- Snake bite envenomation
- Vascular disorders
- Giant haemangioma
- Aortic aneurysm
- Pregnancy-associated:
  - Septic abortion
  - Abruptio placentae
  - Eclampsia
  - Amniotic fluid embolism
  - Placenta praevia
- Burns

Hyperthermia
Liver disease and acute hepatic necrosis

Laboratory Findings

Significant DIC can be present despite normal standard coagulation tests. The key tests in diagnosis are those that provide evidence for excessive conversion of fibrinogen to fibrin and its subsequent lysis. Platelet–fibrin clots create a mesh in the microcirculation in which passing red cells may be damaged, resulting in red cell fragmentation and haemolysis. The blood film may demonstrate fragmentation of the red cells (MAHA), but this is more commonly seen in chronic DIC, especially in association with malignancy.

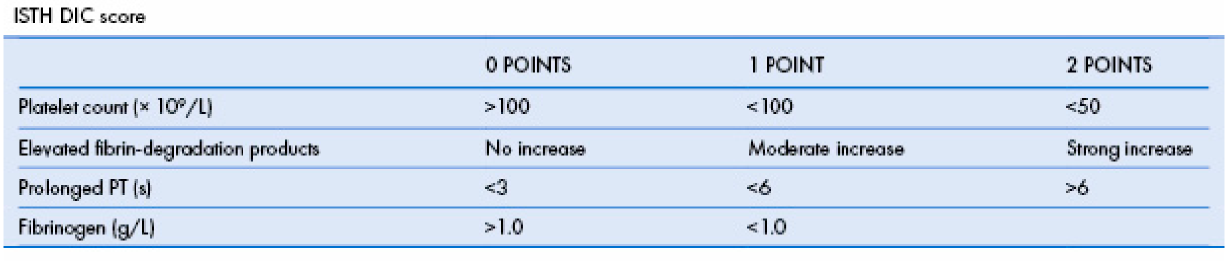
The diagnosis is usually based on a combination of the appropriate clinical picture and laboratory testing of the haemostatic system (Table 113.4). Thrombocytopaenia and hypofibrinogenaemia, with prolongation of the APTT, PT and TCT in conjunction with an elevation of fibrin-degradation products (d-dimer), are indicative of DIC. To assist in the accurate diagnosis of DIC, the International Society on Thrombosis and Haemostasis (ISTH) has developed a scoring algorithm based on laboratory results (Table 113.5).[101, 102]

Table 113.4

Laboratory tests for DIC

ANALYSIS	EARLY	LATE
Platelet count	↓	↓↓
Activated partial thromboplastin time (APTT)	↑	↑↑
Prothrombin time (PT)	↑	↑
Thrombin clotting time (TCT)	↑	↑
Fibrin-degradation products (d-dimer assay)	↑	↑↑
Fibrinogen	↓	↓↓
Other coagulation factors II, VII, VIII, X	↓	↓↓
Coagulation inhibitors: antithrombin III, protein C	↓	↓↓↓
Blood film	Usually normal in early stages	Fragmented red cells can be seen in subacute/chronic cases
Supplementary and research tests – prothrombin fragment 1 + 2, thrombin–antithrombin complex (TAT complex), procalcitonin (PCT), plasmin–antiplasmin complexes (PAP complex)	↑	↑

Table 113.5



ISTH DIC score

	0 POINTS	1 POINT	2 POINTS
Platelet count ($\times 10^9$/L)	>100	<100	<50
Elevated fibrin-degradation products	No increase	Moderate increase	Strong increase
Prolonged PT (s)	<3	<6	>6
Fibrinogen (g/L)	>1.0	<1.0	

From Toh CH, Hoots WK. The scoring system of the Scientific and Standardisation Committee on Disseminated Intravascular Coagulation of the International Society on Thrombosis and Haemostasis: a 5-year overview. *J Thromb Haemost* . 2007;5(3):604-606.

In chronic DIC, the laboratory findings differ from acute DIC, with often normal or near normal haemostasis testing results. Chronic DIC is a compensated state in which there is increased turnover of each of the haemostatic components. D-dimer is elevated in this setting and red cell fragmentation is often seen on the peripheral blood film.

Therapy

The most important measure in the management of DIC is treatment of the initiating cause in conjunction with general resuscitation. Transfusion of blood products has the theoretical risk of ‘feeding the fire’, providing substrates for microthrombi formation. Hence, blood products should be given only to patients with bleeding/high bleeding risk or prior to major procedures. Local institutions routinely establish laboratory parameters to guide transfusion therapy, usually aiming to maintain fibrinogen levels >1.5 g/L and platelet counts $>50 \times 10^9$/L, and INR <1.5.[103] Antifibrinolytic therapy is relatively contraindicated in DIC. Heparin should be used judiciously in the setting of DIC and can be beneficial in settings where major thrombotic complications have occurred. There is no consensus or recommendations regarding timing, dose, or type of heparin to use in DIC. However, it would be prudent to use low doses of UFH initially and up-titrate in the absence of bleeding. In sepsis-induced DIC, there is reduced ATIII activity, however, no study has demonstrated an improvement in mortality with supplemental ATIII therapy. [104] The coagulation inhibitor, recombinant thrombomodulin, showed initial promise in sepsis-induced DIC, but this has not been translated into improved patient outcomes. [105] Despite an increased understanding of the pathophysiology of DIC, unfortunately, there are no specific disease-modifying interventions beyond treating the underlying cause that have demonstrated an improvement in patient outcomes. [106]

Antithrombotic Therapy

The landscape of antithrombotic therapy has changed significantly in recent times with the wide availability of direct oral anticoagulants (DOAC). DOACs are the preferred anticoagulant over vitamin K antagonists (VKA) in the setting of acute venous thromboembolism (VTE) and stroke prevention in the setting of non-valvular atrial fibrillation (AF). [107,108] However, VKA remains the agent of choice for mechanical cardiac valves and high-risk antiphospholipid syndrome. Clinicians must be aware of both the thrombotic and bleeding risks associated with continuing or withholding antithrombotic therapy. With all antithrombotic therapies, the cornerstones of management of major bleeding are investigations for a source of bleeding, cessation of antithrombotics, and local haemostatic and resuscitation measures. Non-specific prohaemostatic agents such as PCC and rFVIIa can be used depending on the antithrombotic therapy administered. The recent TGA approval and availability of both Idaracizumab (for the reversal of dabigatran) and Andexanet Alfa (for the reversal of FXa inhibitors) have significantly changed the approach to the management of DOA-associated bleeding.

Vitamin K Antagonists

Warfarin is the most widely available VKA and induces a functional deficiency of the vitamin-K-dependent clotting factors (II, VII, IX and X), causing prolongation of PT/INR. Warfarin reversal is indicated for patients with major bleeding/high risk of bleeding. Rapid reversal is achieved with infusion of PCC (25–50 U/kg) with concurrent administration of intravenous vitamin K. Four-factor PCCs are the first-line treatment in this setting over FFP. [109]

Vitamin K does not act immediately, with effects seen usually within 6 hours. It accomplishes sustained reversal, hence its use as a reversal agent needs to be carefully considered in patients at high risk of thrombotic events e.g. mechanical mitral valves and recent VTE or stroke. [110] For most surgical interventions or invasive procedures, an INR of 1.5 or less is acceptable. This can usually be achieved by temporarily ceasing warfarin. If required, a 5 mg dose of vitamin K can reverse the INR prolongation without causing significant warfarin resistance when the drug is resumed.

Heparins

Heparins act by potentiating the action of antithrombin, a natural anticoagulant. UFH neutralises both thrombin and FXa, unlike the LMWHs, which predominantly neutralise FXa. The anticoagulant effect of UFH is usually measured by prolongation of the APTT. LMWHs do not prolong the APTT, are generally administered on a weight basis and are not routinely monitored by a laboratory test. When monitoring is required, a drug-specific anti-Xa assay can be used.

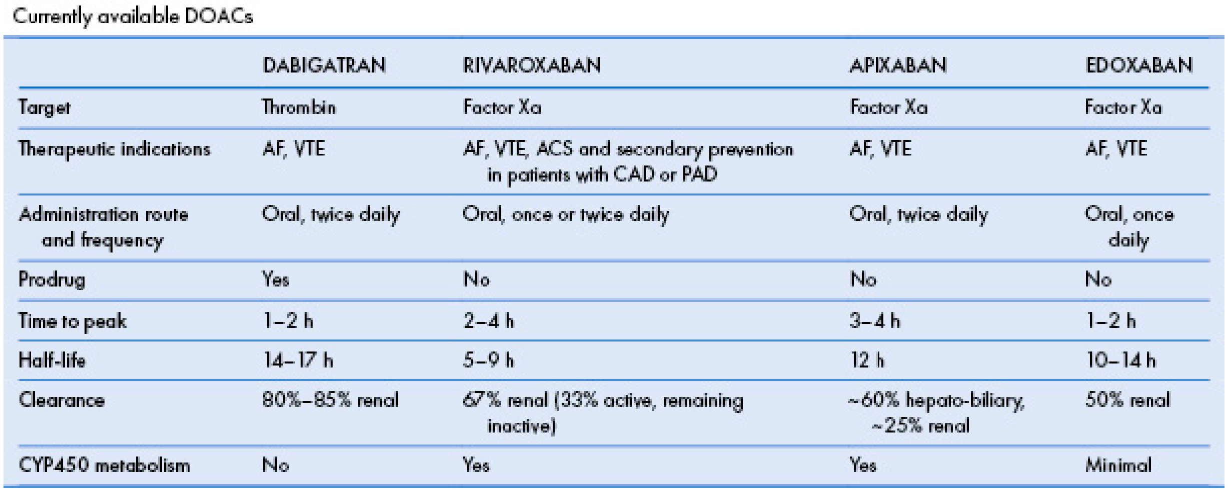
If major bleeding has occurred, immediate reversal of UFH activity can be achieved with protamine sulphate. Protamine itself can paradoxically act as an anticoagulant in excess doses. Doses of protamine required to neutralise 80%–100% of estimated circulating UFH (e.g. 1 mg of protamine sulphate will neutralise 100 units of heparin given in the previous 2–3 hours) have been suggested. [109] It is important to be aware that intravenous administration of protamine can cause acute reactions, including anaphylaxis and acute pulmonary hypertension. Bleeding on LMWH is more difficult to manage than UFH, owing to the longer effective half-life and administration of protamine only partially reverses the effect (1 mg for each 1 mg enoxaparin in the previous 8 hours). Andexanet alfa may have future expanded use for the reversal of enoxaparin, however, it is currently approved only for the reversal of apixaban and rivaroxaban-related bleeding.

Critical illness often involves multiple complex medical issues, including hepatic injury and sepsis which can interfere with accurate APTT interpretation whilst on UFH. Increased doses of UFH (>35,000U/24 hours) to achieve therapeutic APTT should raise the suspicion of heparin resistance. [111-113] This may be secondary to non-specific drug binding (as UFH is negatively charged), ATIII deficiency (related to hepatic dysfunction or nephrotic syndrome) and/or high FVIII levels which is often seen in sepsis, severe illness and in the late stages of pregnancy. It may be useful to measure ATIII levels in such scenarios and use anti-Xa levels to guide UFH therapy (target 0.3-0.7 IU/mL). Alternatively, a direct thrombin inhibitor (i.e. bivalirudin) is an effective alternative to UFH. The replacement of ATIII with human ATIII concentrate ('Thrombotorol') and ongoing titration of UFH is another potential approach but requires further investigation.

Direct Oral Anticoagulants

DOACs target specific coagulation factors, namely FXa (rivaroxaban, apixaban, edoxaban) or thrombin (dabigatran). Given their widespread use, it is important that the critical care physician has a thorough understanding of the mechanism of action, pharmacodynamics and reversal strategies of these agents (Table 113.6). In addition to the currently available FXa and FIIa inhibitors, there are a number of FXI inhibitors undergoing Phase II or III trials which are discussed separately below (Table 113.7). [114] All DOACs are renally excreted to varying extents. Efficacy and safety of DOACs in the management of VTE and stroke prevention in AF have been demonstrated in large randomised control trials, with similar findings reflected in subsequent real-world studies, including the elderly and patients with renal impairment, subpopulations that are particularly at risk of bleeding due to DOACs. [115-117] DOACs offer significant advantages over VKAs, with fixed dosing, and fewer drug and dietary interactions, and they do not require routine laboratory monitoring. All DOACs have shown a significant reduction in intracranial bleeding rates compared to VKA. [118-121]

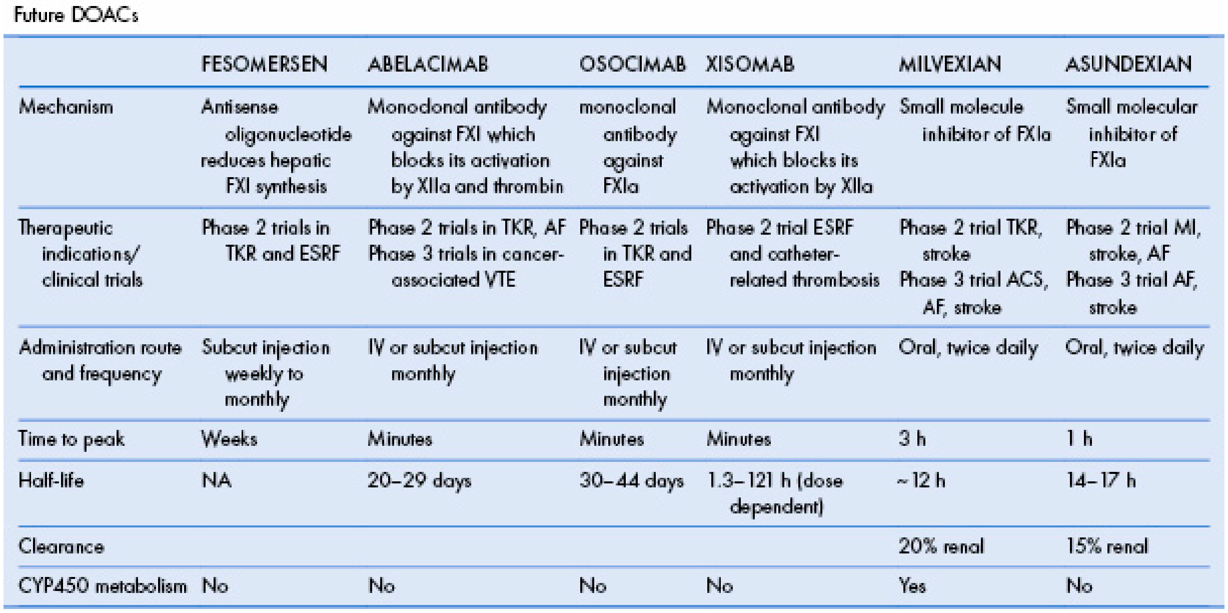
Table 113.6



Currently available DOACs

	DABIGATRAN	RIVAROXABAN	APIXABAN	EDOXABAN
Target	Thrombin	Factor Xa	Factor Xa	Factor Xa
Therapeutic indications	AF, VTE	AF, VTE, ACS and secondary prevention in patients with CAD or PAD	AF, VTE	AF, VTE
Administration route and frequency	Oral, twice daily	Oral, once or twice daily	Oral, twice daily	Oral, once daily
Prodrug	Yes	No	No	No
Time to peak	1–2 h	2–4 h	3–4 h	1–2 h
Half-life	14–17 h	5–9 h	12 h	10–14 h
Clearance	80%–85% renal	67% renal (33% active, remaining inactive)	~60% hepato-biliary, ~25% renal	50% renal
CYP450 metabolism	No	Yes	Yes	Minimal

Table 113.7



Future DOACs

	FESOMERSEN	ABELACIMAB	OSOCIMAB	XISOMAB	MILVEXIAN	ASUNDEXIAN
Mechanism	Antisense oligonucleotide reduces hepatic FXI synthesis	Monoclonal antibody against FXI which blocks its activation by XIIa and thrombin	monoclonal antibody against FXIa	Monoclonal antibody against FXI which blocks its activation by XIIa	Small molecule inhibitor of FXIa	Small molecular inhibitor of FXIa
Therapeutic indications/ clinical trials	Phase 2 trials in TKR and ESRF	Phase 2 trials in TKR, AF Phase 3 trials in cancer-associated VTE	Phase 2 trials in TKR and ESRF	Phase 2 trial ESRF and catheter-related thrombosis	Phase 2 trial TKR, stroke Phase 3 trial ACS, AF, stroke	Phase 2 trial MI, stroke, AF Phase 3 trial AF, stroke
Administration route and frequency	Subcut injection weekly to monthly	IV or subcut injection monthly	IV or subcut injection monthly	IV or subcut injection monthly	Oral, twice daily	Oral, twice daily
Time to peak	Weeks	Minutes	Minutes	Minutes	3 h	1 h
Half-life	NA	20–29 days	30–44 days	1.3–121 h (dose dependent)	~12 h	14–17 h
Clearance					20% renal	15% renal
CYP450 metabolism	No	No	No	No	Yes	No

In patients with major bleeding or requiring emergency surgery, PT (for rivaroxaban), and APTT, TT (for dabigatran) can provide some information on how much drug remains in the patient's circulation and hence contributes to bleeding. Whilst not all laboratory reagents used to measure

PT are sensitive to rivaroxaban, a normal PT utilising a rivaroxaban-sensitive PT reagent and a normal APTT, and in particular a normal TT (dabigatran), in this setting would suggest that DOACs are unlikely to be contributing significantly to major bleeding. Drug-specific assays, in the form of modified factor Xa assays for the factor Xa inhibitors, and dilute TT or the Ecarin clotting time for dabigatran, are available to guide management. As PT and APTT are insensitive to apixaban concentrations, an apixaban-specific FXa assay is required to gauge drug levels. However, these drug-specific factor Xa assays may not be routinely or rapidly available at all sites or after hours. The ClotPro VHA device has assays that show promise for both the detection and quantification of DOAC effect on coagulation parameters. [122], [123]

Apart from major bleeding and peri-operative care, drug levels are also recommended in patients with renal impairment, in patients with recurrent thrombotic events and when non-compliance is suspected. Standard coagulation testing and drug levels are less critical in patients with normal renal function presenting with bleeding in whom the last dose of DOAC was at least 12 hours prior, as the majority of the DOAC would have been eliminated.

Idrarucizumab is a humanised monoclonal antibody fragment with a high affinity for dabigatran. It has no intrinsic procoagulant or anticoagulant activity and is renally excreted. In a large study, of patients with life-threatening bleeding or requiring emergency surgery, idarucizumab given at two 2.5 g intravenous doses (total dose 5 g) resulted in rapid and complete reversal of dabigatran activity that was sustained for greater than 24 hours in nearly all patients with a favourable safety profile. [124] Idarucizumab is now the first-line treatment in dabigatran-related critical bleeding episodes, with haemodialysis an option if the drug is not readily available. Idarucizumab should not be used for bleeding episodes that can respond to local haemostatic measures or prior to non-emergent surgery.

Andexanet alfa is a recombinant modified human factor Xa protein, which, whilst catalytically inactive, reversibly binds to and sequesters FXa inhibitors, allowing endogenous factor Xa activity to be restored. It is able to reverse the activity of rivaroxaban and apixaban. [125] Andexanet alfa is administered as a bolus dose based on the dose of FXa inhibitor the patient has taken, and the estimated time elapsed since the last dose, (within 18 hours) followed by a continuous infusion to ensure sustained reversal. The ANNEXA-A and ANNEXA-R studies showed effective reduction in anti-Xa inhibitor activity using Andexanet alfa in healthy volunteers administered apixaban and rivaroxaban respectively. [126] The haemostatic efficacy of andexanet alpha in patients presenting with acute major bleeding related to FXa inhibitors has been demonstrated in the ANNEXA-4 study. [127] However, there is some controversy regarding the use of andexanet alpha in routine clinical practice due to its cost, risk of thrombotic complications and the fact that its comparative efficacy against four-factor PCC has not been evaluated. [128] Clinicians need to be mindful of the cost and potential for thromboembolic complications when utilising specific DOAC reversal agents and their use should be restricted to those patients that definitively require them and in consultation with haematology (Fig. 113.5).

Bleeding patient on DOAC

STOP DOAC

☐ Confirm dose and time of last drug intake
☐ Initiate standard resuscitation procedures as required
☐ Urgent coagulation screen (APTT, PT fibrinogen), FBE, UEC +/- VHA
☐ Consider medication specific anti-Xa level (Apixaban/ Rivaroxaban) or Haemoclot (Dabigatran) - indicate name, dose and time of last dose on request
☐ Consult Haematology early

	Dabigatran	Rivaroxaban	Apixaban
APTT	↑↑↑	↑	↑
PT/INR	↑	↑↑	↑↑
TT	↑↑↑↑	No effect	No effect
Drug specific assays	Haemaclot & Ecarin clotting time	Anti-Xa	Anti-Xa

normal coagulation profile **DOES NOT** exclude clinically significant amount of DOAC on board

Bleeding Severity

MILD

Local haemostatic measures, mechanical compression +/- surgical intervention

Delay next DOAC dose and review need for ongoing anticoagulation

MODERATE

Clinically Significant
Hb drop >20g/L
Transfusion >2U RBCs

Consult Haematology

Consider activated charcoal 50g STAT if DOAC <6h prior

Local haemostatic measures, mechanical compression +/- surgical intervention

Maintain adequate hydration and renal function to aim DOAC clearance

Transfusion support

Consider TXA 1g STAT following by 1g infusion over 8 hours (except in GIT bleeding)

Consider 10mg IV Vit K if INR >1.5

If ongoing bleeding with haemodynamic instability despite above, consider pro-haemostatic measures as described for severe bleeding

LIFE THREATENING

Bleeding in critical area/organ, compartment syndrome, hypotension not responding to resuscitation

Consult Haematology + Critical care services

Institute measures as for moderate bleeding & activate MTP if appropriate

Consider drug specific reversal agents:

Andexanet Alfa (Apixaban/ Rivaroxaban)
- Low dose: 400mg IV, then 480mg IV over 2h
- High dose: 800mh IV, then 960mg IV over 2h

Idarucizumab (Dabigatran)
- 5g IV in total

If targetted reversal agents are not availble:
- aPCC 50IU/Kg IV or
- rFVIIa 30mcg/Kg IV

Consider TXA 1g STAT following by 1g infusion over 8 hours (except in GIT bleeding)

Consider 10mg IV Vit K if INR >1.5

The clinical decision flowchart for managing a bleeding patient on direct oral anticoagulants begins with stopping direct oral anticoagulants therapy and confirming the drug dose and timing. Initial steps include resuscitation, coagulation screening with A P T T, P T or I N R, fibrinogen, F B E, U and E, and optional V H A. A table outlines expected coagulation effects of dabigatran, rivaroxaban, and apixaban on A P T T, P T or I N R, and T T, with dabigatran exhibiting increased times and an anti two a effect, while rivaroxaban and apixaban show anti ten a effects. A note warns that normal coagulation results do not exclude significant circulating drug levels. Bleeding is categorised as mild, moderate, or life-threatening. Mild bleeding involves local measures and direct oral anticoagulants delay. Moderate bleeding includes haemoglobin drop over 20 grams per litre or transfusion of more than two red blood cell units, requiring haematology consultation, possible charcoal administration, mechanical measures, and hydration. Treatments include tranexamic acid and vitamin K if I N R is elevated. Life-threatening bleeding involves critical organ or volume compromise and unresponsiveness to resuscitation.

FIG. 113.5 DOAC Bleeding Management.

Factor XI Inhibitors

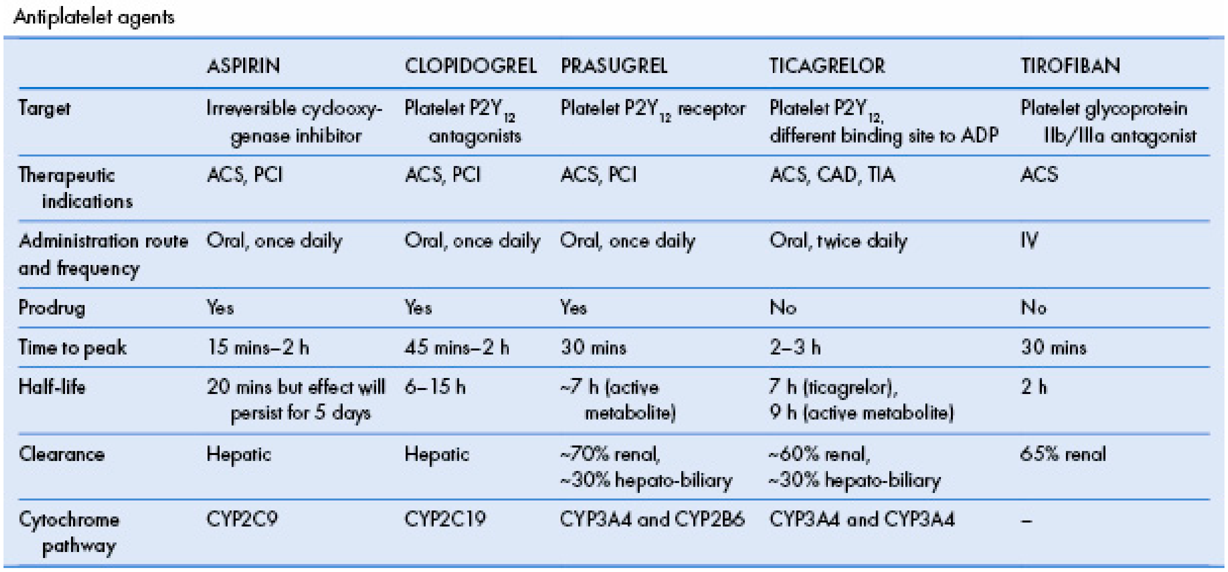
A number of FXI inhibitors are currently in different stages of clinical development and may be encountered more frequently in the critical care setting in the future (Table 113.7). Unlike the other DOAC targets, FXa and thrombin, which are critical for fibrin formation and hence essential for haemostasis as well as pathological thrombosis, FXI is part of the early intrinsic pathway of coagulation with a lesser contribution to haemostasis. FXI is therefore viewed as a potential ‘holy grail’ for targeted anticoagulation due to its inhibition resulting in effective anticoagulation without an increased risk of bleeding.

Fesomersen is an antisense oligonucleotide that reduces the synthesis of FXI by binding to FXI messenger RNA in hepatocytes and inducing its degradation. Osocimab, abelacimab and xisomab (AB023) are antibodies that inhibit FXIa whilst asundexian and milvexian are small molecules that bind the active site of FXIa inhibiting its activity.[129] Added novel properties of some of these agents include a single dosing protocol with drug activity lasting weeks to a month and safety in end-stage renal failure.

Antiplatelet Agents

Antiplatelet agents are used widely for the treatment of arterial disease, and many of the non-steroidal anti-inflammatory agents (NSAIDs) are also platelet-inhibitory drugs (Table 113.8). Aspirin has an irreversible effect on platelet function and platelet function tests may show abnormalities for up to 10 days after medication. $P2Y_{12}$ antagonists include clopidogrel, prasugrel and ticagrelor. Prasugrel and ticagrelor have a more rapid onset of action than clopidogrel, with antiplatelet effects within 2–4 hours. These drugs inhibit the binding of ADP to its platelet receptor $P2Y_{12}$, thus suppressing ADP-mediated activation of the GP IIb/IIIa complex. As with aspirin, platelets exposed to $P2Y_{12}$ antagonists are affected for their lifespan (5–10 days) and recovery of normal platelet function occurs as new platelets are produced. $P2Y_{12}$ antagonists are thought to be more potent than aspirin in antiplatelet effect and hence associated with higher bleeding risk.[110, 130] Prasugrel achieves more predictable antagonism of ADP compared with clopidogrel, at the expense of increased bleeding. The bleeding risk is also high with ticagrelor.[131] The bleeding risk associated with antiplatelet agents is increased with the use of dual antiplatelet therapy of increasing duration, particularly with drug-eluting coronary stents and the risk of late in-stent thrombosis.

Table 113.8



Antiplatelet agents

	ASPIRIN	CLOPIDOGREL	PRASUGREL	TICAGRELOR	TIROFIBAN
Target	Irreversible cyclooxygenase inhibitor	Platelet $P2Y_{12}$ antagonists	Platelet $P2Y_{12}$ receptor	Platelet $P2Y_{12}$, different binding site to ADP	Platelet glycoprotein IIb/IIIa antagonist
Therapeutic indications	ACS, PCI	ACS, PCI	ACS, PCI	ACS, CAD, TIA	ACS
Administration route and frequency	Oral, once daily	Oral, once daily	Oral, once daily	Oral, twice daily	IV
Prodrug	Yes	Yes	Yes	No	No
Time to peak	15 mins–2 h	45 mins–2 h	30 mins	2–3 h	30 mins
Half-life	20 mins but effect will persist for 5 days	6–15 h	~7 h (active metabolite)	7 h (ticagrelor), 9 h (active metabolite)	2 h
Clearance	Hepatic	Hepatic	~70% renal, ~30% hepato-biliary	~60% renal, ~30% hepato-biliary	65% renal
Cytochrome pathway	CYP2C9	CYP2C19	CYP3A4 and CYP2B6	CYP3A4 and CYP3A4	–

Clinicians are now regularly confronted with balancing the haemorrhagic risks associated with these agents against the thrombotic risks associated with their discontinuation, either during major bleeding episodes or prior to surgery. As there is no direct reversal agent, bleeding in the setting of antiplatelet therapy is managed mainly by the cessation of the drug and general haemostatic measures. Desmopressin has been shown to correct aspirin-induced platelet dysfunction, although clinical outcome data are limited. [132]

Platelet transfusions are often used in acute life-threatening bleeding or prior to emergency surgery in the setting of antiplatelet therapy. [133] However, timing and dosing remain unclear. Platelet transfusions appear to be more effective in reversing platelet dysfunction attributable to aspirin. [134] Ex-vivo studies have demonstrated that correction of clopidogrel-induced abnormal platelet aggregation responses required a higher proportion of donor platelets than aspirin. Platelet transfusions have been reported to be ineffective in reversing the effects of ticagrelor. [135] Continuing aspirin in the peri-operative period of most invasive procedures, neuroaxial anaesthesia and coronary artery bypass surgery is reasonable. [110], [136] If bleeding risk is deemed to be too high, clopidogrel and ticagrelor should be withheld for 5 days, and prasugrel for 7 days prior to major surgery. Normal platelet function is restored more rapidly upon cessation of GP IIb/IIIa inhibitors, more so with tirofiban and eptifibatide (4–8 hours) than abciximab (1–2 days). Hence withdrawal of these drugs is usually sufficient for most bleeding episodes in the absence of thrombocytopaenia. Platelet transfusions are recommended with abciximab-associated thrombocytopaenia (platelet count $<10 \times 10^{9}$/L).

The lack of clear efficacy of platelet transfusions in major bleeding with concurrent antiplatelet therapy was further highlighted by the landmark randomised open-labelled Phase III PATCH trial that demonstrated platelet transfusions, rather than benefiting patients, was associated with poorer outcomes in patients with stroke due to spontaneous, non-traumatic intracerebral haemorrhage. [137]

Acquired Coagulation Inhibitors

Major bleeding can be seen with rare inhibitors of coagulation factors. Autoantibodies against FVIII (commonest), IX, X, V and VWF have been reported. Bypassing agents, such as rFVIIa, activated PCCs, such as FEIBA and recombinant porcine FVIII, have been shown to be efficacious in arresting bleeding in this setting, particularly high-titre inhibitors. The other main aim of treatment is antibody eradication. Steroids and cyclophosphamide, as well as rituximab, have been used to achieve this aim. In acute emergencies, particularly in patients with high-titre inhibitors in whom bleeding has not responded to bypass agents, plasmapheresis with an immunoadsorption column can be used. [138]

Case Vignette 1: ECMO and Heparin Resistance

A 54-year-old male with respiratory failure secondary to influenza pneumonia complicated by bacterial superinfection is on VV-ECMO. The patient also has an element of ischaemic hepatitis presumed secondary to severe sepsis and hypoperfusion. UFH is used for anticoagulation and is uptitrated in the setting of deterioration in oxygenator function. Over the following 72 hours, the UFH dose progressively increases to more than 1500 units/h which is only achieving an APTT level just above the lower limit of normal and two circuit changes have been required. Given the concurrent hepatic dysfunction, an anti-Xa level is performed which returns at only 0.2 IU/mL. Acquired ATIII deficiency is suspected in the setting of hepatic failure and an ATIII level returned at only 34%. The patient's anticoagulation was changed to bivalirudin to avoid the ATIII-dependent nature of UFH and appropriate institution-specific APTT targets used for monitoring. Thrombotrol (ATIII concentrate) supplementation and continuation of UFH is another approach to heparin resistance. A consensus approach to the management of heparin resistance is not established, however, anti-Xa monitoring should be considered where the APTT appears out of keeping with the doses of UFH being used and especially in patients with an increased bleeding risk.

It is also important to note the impact of elevated FVIII levels, which often occur in severe sepsis and illness, contributing to heparin resistance and lower than predicted or 'subtherapeutic' APTT levels. The patient achieved target APTT levels on bivalirudin without the need for any further circuit changes.

Case Vignette 2. Complex Multifactorial Coagulopathy

A 73-year-old female presents with cardiac arrest due to cardiac tamponade 2 weeks following a diagnosis of proximal lower limb DVT and large bilateral PE. She is on therapeutic apixaban 5 mg BD on presentation with her last dose being that morning. The patient has ROSC following CPR and a pericardial drain is inserted with restoration of haemodynamics. In the context of her recent PE with large clot burden demonstrated on CT pulmonary angiogram (CTPA) and risk of VTE extension, a UFH infusion is commenced after a period of haemodynamic stability and minimal output from pericardial drain. 24 hours after commencement of the heparin infusion further bleeding is noted from the pericardial drain. She has a complex and multifactorial coagulopathy due to ischaemic hepatitis, delayed hepatic clearance of apixaban, UFH effects and presumed sepsis.

Her INR is 3.5, APTT 39 and FibC 2.9. An anti-Xa level is sent to guide UFH given the likely acquired ATIII deficiency and the difficulties in interpreting APTT in this context. The anti-Xa level is elevated at 1.41 despite an APTT only just above the normal range (which likely reflects a combination of UFH and apixaban activity). The heparin infusion is stopped, FFP, Vitamin K and PCC are administered to support the hepatic coagulopathy and the anti-Xa level is used to monitor clearance of apixaban and to guide when it's safe to recommence UFH. Once the APTT normalises and the anti-Xa level is <0.7, UFH is slowly recommenced with close monitoring of hepatic function.

This case highlights a complex multifactorial coagulopathy related to ischaemic hepatitis and DOAC effect. It is important to recognise the impact of delayed hepatic as well as renal clearance of DOACs in this setting and the utility of specialised coagulation investigations to guide management.

Case Vignette 3: Thrombocytopaenia

A 70-year-old female was discharged following exploratory laparotomy for perforated duodenal ulcer with peritonitis. The patient represented 4 days after discharge with right-sided pleuritic chest pain and hypoxia due to right-sided hospital-acquired pneumonia. Her platelet count was 160×10^{9}/L at this time, and she was commenced on appropriate IV antibiotics including vancomycin and cefepime. On day 2 of her hospital admission, the patient showed improvement in her clinical parameters; however, her platelet count was now 118×10^{9}/L. Later that day she developed left knee pain with associated swelling of the entire leg. An urgent ultrasound confirmed a DVT, and the patient was commenced on a UFH infusion. A DOAC was avoided due to recent surgery. On day 5 her platelets had dropped further to 85×10^{9}/L. Her 4T score was elevated at 4 and a HIT ELISA was positive. Confirmatory testing with a serotonin release assay was also positive and consistent with a diagnosis of HIT. The patient's UFH anticoagulation was stopped and changed to a thrombin inhibitor. Over the following days, her platelet count improved to 210×10^{9}/L.

Summary

Haemostatic failure is a complex, dynamic and often multifactorial process in the critical care environment. The underlying disease pathology, associated co-morbidities and drug therapies can all impact the finely balanced haemostatic system in the critically ill patient, resulting in an increased risk of bleeding, thrombosis or both. The understanding of normal haemostasis has evolved significantly with the appreciation of a cell-based model of haemostasis and there have been significant advances in the assessment and diagnosis of haemostatic failure. VHA provide a more complete picture of the haemostatic system and can potentially assist in guiding therapy in a timely manner. Increased understanding of the pathogenesis of TMAs has resulted in a more accurate classification of specific disease subtypes and the use of targeted therapies for aHUS. Targeted therapies are also often available for congenital bleeding disorders, which although rare can present for the first time after major surgery or trauma. Drug-specific assays for the DOACs are available along with effective reversal agents for dabigatran and factor Xa inhibitors. There have been fewer advances made in the management of bleeding in the setting of antiplatelet therapy, with a lack of clear benefit derived from platelet transfusions and no specific reversal agents. The increased uptake of extracorporeal organ support therapies presents the intensivist with unique challenges in managing the delicate balance between bleeding and thrombosis. The complex nature of haemostatic failure in critical illness requires the close collaboration of the intensivist and haematologist to ensure timely diagnosis and treatment.

Haematological malignancy

Pascale Gruber, Timothy Wigmore and Sef Carter

Introduction

Haematological malignancies are tumours that involve the bone marrow, blood and lymphoid tissue and account for 6.6% of all new cancer diagnoses per year.[1] Patients with haematological malignancy account for 2.1% of ICU admissions with a reported in-hospital mortality rate of 41.1% in the United Kingdom.[2] Systemic anti-cancer therapy (SACT) refers to all cytotoxic drugs and immunotherapies, used in the treatment of solid organ or haematological malignancy.

Classification of Haematological Malignancies

Traditional descriptive epidemiology divides haematological malignancies into four broad categories: leukaemias, Hodgkin lymphomas, non-Hodgkin lymphomas and myelomas, with national and international organisations publishing data in this format.[1,3,4] The World Health Organisation (WHO) classifies haematological malignancies according to lineage, and the dominant clinical and biological attributes. Disease lineage is determined by immunophenotyping with flow cytometry and cytogenetic and molecular genetic analysis of peripheral blood and bone marrow samples. Clinical attributes are descriptive of untreated disease and include descriptors such as acute, chronic, cytopenias (myelodysplasia) and cytosis (myeloproliferation). Biological attributes include genetic mutations, fusions and rearrangements. [5]

Leukaemia

Over 450,000 people are diagnosed with leukaemia worldwide each year. [1] Presenting features include fatigue, lymphadenopathy, hepatosplenomegaly and general symptoms of bone marrow failure such as anaemia, bleeding and decreased resistance to infection with blast cells observed on blood films. The severity of disease, rate of progression and treatment varies between leukaemias, so precise identification of the specific form of leukaemia is crucial. Acute leukaemias where both myeloid and lymphoid cells are present, or where the blast population does not allow classification in myeloid or lymphoid categories are grouped together due to overlapping clinical and immunophenotypic features.

Acute Lymphoblastic Leukaemia (ALL)

ALL is a malignant disorder of lymphoid precursor cells affecting either T-cells or B-cells. Paediatric ALL has a very good prognosis with a cure rate of >90%, whilst adult cases have a 5-year cure and survival rate of less than 40%. [6] There is a biphasic incidence of ALL with most cases arising in children aged 1–4 years old, with 60% of cases occurring in those less than 20 years old. This is followed by a gradual increase in incidence in those older than 45 years of age. [7]

Following induction chemotherapy, patients will typically undergo either haematopoietic stem cell transplantation (HSCT), or consolidation and intensification SACT. Due to the high incidence of central nervous system (CNS) disease at diagnosis, routine intrathecal chemotherapy or intracranial radiotherapy is commonplace for non-transplanted patients. [8] Patients managed without transplantation will typically continue maintenance chemotherapy for 2–3 years. [9] Mutations such as the BCR::ABL1 (Philadelphia chromosome) positive ALL have historically been associated with poor outcomes; however, the use of tyrosine kinase inhibitors (TKIs) in patients not suitable for HSCT has improved remission rates. [10]

Acute Myeloid Leukaemia (AML)

AML is the most common acute leukaemia in adults and is characterised by uncontrolled proliferation of immature myeloid precursor cells. When untreated, death is usually due to infection or bleeding within months of diagnosis. There are various subtypes of AML classified by recognised genetic abnormalities, the cell lineage involved, the presence of myelodysplasia-related features, cases arising post-cytotoxic treatment or in patients with predisposing genetic abnormalities or with a tissue-based manifestation of AML. [5] Despite novel therapies targeting pathological signalling pathways, enzymes and co-stimulatory receptors, the 5-year survival due to AML is <25%, with a median survival time of less than 9 months from diagnosis. [11] Following induction SACT, patients will be considered for consolidation SACT or HSCT. Transplantation is typically reserved for patients less than 60 years old. Unlike ALL, CNS disease is not frequently observed, and routine prophylaxis is not required.

Acute promyelocytic leukaemia t(15:17) (APML) is a subtype of AML and has a classic morphology with dense cytoplasmic granules and Auer rods. Promyelocytes release thromboplastins resulting in disseminated intravascular coagulation (DIC) and intracranial or pulmonary haemorrhage is an important cause of early mortality. [10] All-trans retinoic acid (ATRA) targets the PML/RARα gene promoting maturation of leukaemic cells and is used during induction therapy. When combined with arsenic trioxide (ATO), 2-year overall survival exceeds 95%. [12] Differentiation syndrome, formerly known as retinoic acid syndrome, is a potentially life-threatening complication of ATRA therapy. Symptoms usually begin within the first 30 days of ATRA therapy and include respiratory failure, fever, weight gain, peripheral oedema, shock, acute kidney injury, cardiac failure, pericardial and pleural effusions. An increase in white blood cell count above 10×10^9/L following treatment is a sign of differentiation syndrome. Corticosteroids and temporary discontinuation of ATRA are standard practice. [13]

Chronic Lymphocytic Leukaemia (CLL)

CLL may be classified as a form of leukaemia or low-grade lymphoma. It is typically observed in elderly patients, with a median age at diagnosis of 70 years. Clinical presentation includes fatigue, bone marrow failure, night sweats, lymphadenopathy, painful splenomegaly and autoimmune haemolytic anaemia. 5-year survival in those less than 60 years old is 95%. [13] Patients who undergo histological transformation of CLL to a more aggressive form of large cell lymphoma (Richter's syndrome), such as diffuse large B-cell lymphoma, have a remission rate of 20%. [14] Treatment is typically initiated in the presence of cytopenias, massive/symptomatic lymphadenopathy or organomegaly and disease-related constitutional symptoms such as fever, fatigue and night sweats. [15]

Chronic Myeloid Leukaemia (CML)

CML is defined by the BCR::ABL1 fusion gene due to reciprocal translocation between chromosome 9 and 22 (Philadelphia chromosome, t(9;22)(q34;q11)) resulting in uncontrolled proliferation of multipotent progenitor myeloid cells. Untreated, the disease takes an indolent course lasting several years before progressing to an accelerated phase and finally, a blast phase characterised by a blast cell count ≥20%. Treatment with the TKI, Imatinib, has increased the 10-year survival of CML to 80%–90% and reduced the incidence of the accelerated phase. [16] Mutations of the BCR::ABL1 gene are observed in up to 80% of cases of blast crisis, with continued activity of this mutation resulting in further genetic instability and impaired DNA repair.

Myelodysplastic Neoplasms

Myelodysplastic/myeloproliferative neoplasms (MDN) comprise a heterogeneous group of rare malignancies which typically display unbalanced chromosomal translocations. [17] Myelodysplastic neoplasms are usually diagnosed in patients over 65 years old, presenting with symptoms of bone marrow failure. Bone marrow examination demonstrates features such as hypercellular bone marrow with atypical megakaryocytes, and ring sideroblasts. Most patients will be considered for non-invasive therapies with the intent of improving quality of life and reducing the risk of bleeding or infection-related complications. [18], [19] Allogenic HSCT is considered in fit patients with risk factors for severe disease and select patients who have low-risk disease but have failed first-line therapies. [20] Some patients will transform to develop AML. [21]

Lymphoma

Lymphomas are tumours of B, T or NK lymphoid cells. Traditionally, lymphomas are divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL), with Reed-Sternberg cells being the histological hallmark feature of Hodgkin lymphoma. Lymphomas are staged 1–4 according to lymph node spread and designated A or B depending on the absence or presence of ‘B’ symptoms – night sweats, fever and weight loss.

Hodgkin Lymphoma

HL is the most common cancer of teenagers. Risk factors include male sex, prior infection with Epstein-Barr virus (EBV) or human immunodeficiency virus, autoimmune disease and smoking. [22] Classic presentation is with painless cervical lymphadenopathy, fever, night sweats, weight loss and pruritis. Radiotherapy may be used for localised or bulky diseases. [23] Combination chemotherapy with or without radiotherapy is curative in over 90% of patients with stage I or II Hodgkin disease. [24]

Non-Hodgkin Lymphoma

NHL is a heterogeneous group of conditions with over 30 subtypes. NHLs are broadly divided into high and low grades. High-grade lymphomas tend to be aggressive but chemo-sensitive, whereas low-grade lymphomas are typically slow-growing, indolent and incurable. [25]

Low-grade lymphomas

Low-grade lymphomas encompass follicular lymphoma (most common), mantle cell lymphoma, marginal zone lymphomas and Waldenstrom macroglobinaemia. A watch-and-wait strategy is often appropriate due to the slowly progressive nature of these malignancies in asymptomatic patients. [26], [27]

High-grade lymphomas

The most common high-grade lymphoma is diffuse large B-cell lymphoma (DLBCL), accounting for about 30% of cases, and typically affects elderly or middle-aged adults. First-line treatment includes R-CHOP chemotherapy (rituximab, cyclophosphamide, doxorubicin, vincristine and prednisolone) with or without involved field radiotherapy. [28] Following treatment, progression-free survival approaches 5 years, with a median overall survival of 8.4 years. [29] Relapsed and refractory cases remain an important cause of mortality despite second- and third-line treatment. [30]

Multiple Myeloma

Multiple myeloma accounts for over 15% of all haematological malignancies. Patients present with bone pain, fractures and bone marrow failure with associated cytopenias. Renal failure is common due to light chain deposition in the renal tubules, amyloidosis and hypercalcaemia. Multiple myeloma is incurable, but chemotherapy induces temporary remission. Typically, patients experience repeated episodes of relapse, treatment and remission over several years until the disease can no longer be controlled. The 5-year survival for multiple myeloma is around 60%. [31] HSCT and chimeric antigen receptor-expressing T cells (CAR-T cells) therapies may be considered in refractory cases. [32], [33]

Treatment of Haematological Malignancies

Haematological malignancies are treated using SACT, radiotherapy or a combination of both with the intent of inducing remission or cure. Immunotherapy in the form of monoclonal antibodies, checkpoint inhibitors, cytokine therapy and adaptive T-cell therapy has dramatically increased treatment options for relapsed or refractory disease. Furthermore, monoclonal antibodies are the first line in the treatment of certain malignancies, such as CML. HSCT, however, remains the only curative option in several malignancies. Due to the treatment-associated toxicity and risk of subsequent complications HSCT is reserved for patients with a good performance status.

Chemotherapy

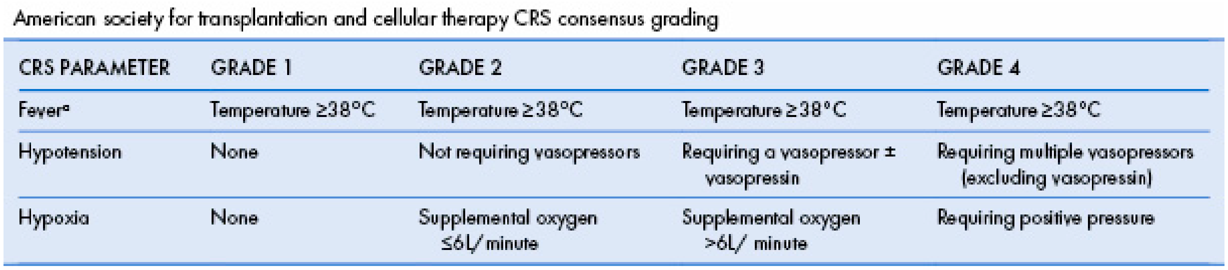
Chemotherapeutic agents, either individually or in combination, are used to induce cure or remission. Those commonly used agents are outlined in Table 46.1 of the Solid tumour chapter. The goal of *induction therapy* is to achieve remission by reducing the number of malignant cells to an undetectable level; the goal of *consolidation therapy* is to eliminate any residual undetectable disease and achieve a cure. *Maintenance therapy* is used to prolong remission. Administration of some chemotherapeutic agents may result in life-threatening side effects, notably neutropenic sepsis.

Immunotherapy

Immunotherapy augments the adaptive immune system response to overcome malignant cell mechanisms of immunosurveillance escape, such as defective antigen presentation and upregulation of negative regulatory pathways. Adoptive cellular therapies such as CAR-T and T-cell receptor (TCR)-engineered cells are increasingly utilised in the management of refractory ALL and NHL.[34] CAR-T cell therapies are associated with multiple toxicities such as anaphylaxis, on-target/off-target effects (such as B-cell aplasia), hemophagocytic lymphohistiocytosis (HLH), cytokine release syndrome (CRS) and immune effector cell-associated neurotoxicity syndrome (ICANS). There is great variability in the reported incidence of these toxicities; however, patients with a greater burden of malignant disease and higher CAR-T cell doses are associated with an increased risk of severe CRS and ICANS.[35] Toxicities typically develop within the first 14 days.

CRS is a systemic inflammatory response initiated by CAR-T cell cytokines, characterised by fever, hypotension and hypoxia. It frequently starts within hours of cell infusion and lasts for several days. Multiple grading systems exist for CRS; however, the requirement for vasopressors and supplemental oxygen ($FiO_2 \geq 0.40$) define severe CRS (grade III–IV) in all grading systems (see Table 114.1).[36] Anti-cytokine therapy with tocilizumab, a monoclonal antibody targeting the IL-6 receptor, remains at the forefront of CRS management to reduce the dysregulated inflammatory response and is effective in preventing the progression to severe or life-threatening CRS. In ALL, administration of Tocilizumab does not reduce the risk of complete remission, although concerns remain regarding the duration of CAR-T cell anti-tumour effect following tocilizumab. [37] Multiple doses of tocilizumab alongside corticosteroids should be considered if there is no improvement, or there is progression of CRS. Refractory cases with life-threatening toxicity may be managed with biological agents such as Anakinra (an IL-1 receptor antagonist) and escalating doses of corticosteroids. [38], [39] Etoposide has an established role in the management of secondary HLH and may be considered in refractory CRS although there is limited published evidence to support this. [40]

Table 114.1



American society for transplantation and cellular therapy CRS consensus grading

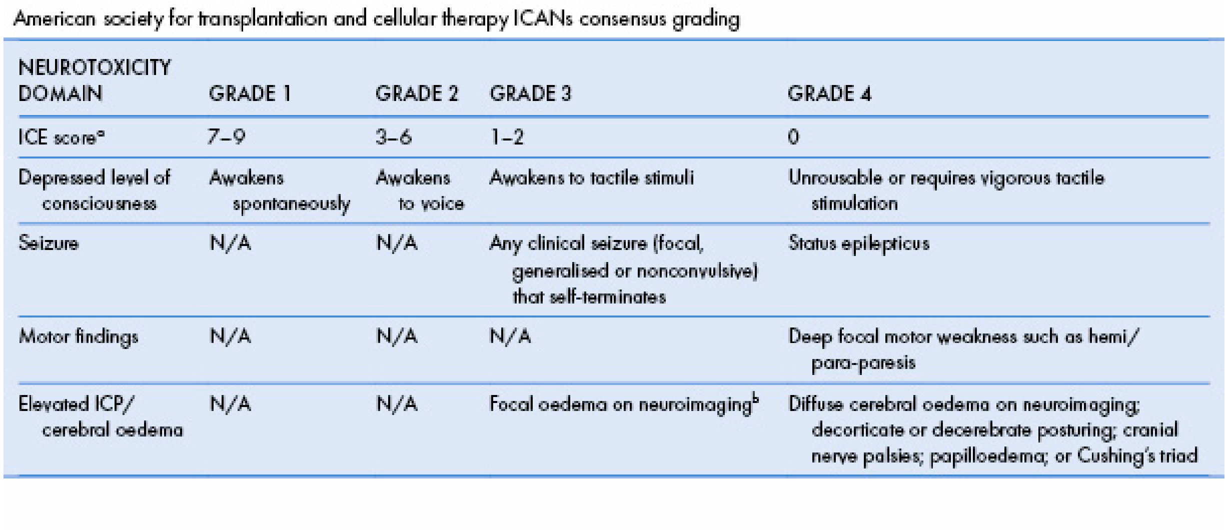
CRS PARAMETER	GRADE 1	GRADE 2	GRADE 3	GRADE 4
Fever[a]	Temperature ≥38°C	Temperature ≥38°C	Temperature ≥38°C	Temperature ≥38°C
Hypotension	None	Not requiring vasopressors	Requiring a vasopressor ± vasopressin	Requiring multiple vasopressors (excluding vasopressin)
Hypoxia	None	Supplemental oxygen ≤6L/ minute	Supplemental oxygen >6L/ minute	Requiring positive pressure

[a] Fever is defined as temperature ≥38°C not attributable to any other cause.

CRS , cytokine release syndrome.

ICANS typically presents as an encephalopathy developing independent of CRS, or shortly after CRS has developed. Word-finding difficulty, headache, aphasia and tremors are common clinical findings. Signs of encephalopathy should be serially assessed with the 10-point Immune Effector Cell Encephalopathy (ICE) score. [41] ICANS is a clinical diagnosis, however, contrast-enhanced MRI of the brain/spinal cord in addition to adjunct tests such as EEG and CSF analysis may be useful to rule out alternative diagnoses such as infection or venous sinus thrombosis. Severity grading is defined according to the ICE score, and clinical signs (see Table 114.2). The management of Grade 1 ICANS involves avoiding sedative drugs, regular neurological review and minimising aspiration risk. Corticosteroids with or without IL-1 receptor antagonists form the cornerstone of management for grades 2–4.[39, 42] High cumulative doses of corticosteroids may reduce progression-free survival and should therefore be weaned in response to clinical improvement.[43] Surgical decompression may be considered in cases with raised intracranial pressure (ICP). Tocilizumab is not effective and has been suggested to worsen the severity of ICANS.[44, 45]

Table 114.2



American society for transplantation and cellular therapy ICANs consensus grading

NEUROTOXICITY DOMAIN	GRADE 1	GRADE 2	GRADE 3	GRADE 4
ICE score[a]	7–9	3–6	1–2	0
Depressed level of consciousness	Awakens spontaneously	Awakens to voice	Awakens to tactile stimuli	Unrousable or requires vigorous tactile stimulation
Seizure	N/A	N/A	Any clinical seizure (focal, generalised or nonconvulsive) that self-terminates	Status epilepticus
Motor findings	N/A	N/A	N/A	Deep focal motor weakness such as hemi/para-paresis
Elevated ICP/ cerebral oedema	N/A	N/A	Focal oedema on neuroimaging[b]	Diffuse cerebral oedema on neuroimaging; decorticate or decerebrate posturing; cranial nerve palsies; papilloedema; or Cushing's triad

[a] A patient with an ICE score of 0 may be classified as grade 3 ICANS if awake with global aphasia, but a patient with an ICE score of 0 may be classified as grade 4 ICANS if unarousable.

[b] Intracranial haemorrhage with or without associated oedema is not considered a neurotoxicity feature and is excluded from ICANS grading.

ICANS , immune effector cell-associated neurotoxicity syndrome.

Radiotherapy

Radiotherapy can be used alone or in combination with chemotherapy for lymphoma and myeloma. TBI may be instituted as part of the myeloablative regime in HSCT. Side effects include gastrointestinal dysfunction, mucositis, pneumonitis, alopecia and skin irritation.

Haematopoietic Stem Cell Transplantation (HSCT)

Over 80,000 transplants are carried out per year globally. [46] Up to 20% of allogenic transplants will require admission to ICU compared to 3% of autologous transplants. The 1-year survival of allogenic HCST patients is 60%–70%, however, survival falls to <30% for patients who require admission to ICU. [47–50] Myeloablative conditioning is required prior to transplantation to destroy endogenous bone marrow cells and lower the malignant burden. Reduced-intensity conditioning regimes are reserved for patients who are older, have multiple co-morbidities or have undergone previous transplants.

HSCT are divided according to the source of the stem cells (peripheral, bone marrow or umbilical cord) and the donor of the cells (autologous or allogeneic). Autologous transplantation involves re-infusing harvested peripheral blood stem cells taken from the patient during periods of remission. With autologous transplants, patients risk the possibility of re-infusion of the patient’s tumour cells. Allogenic transplants involve the infusion of donor stem cells (related or unrelated donors). Immunosuppression is required to reduce the risk of graft versus host disease (GVHD) and graft rejection. Whilst overall survival has improved over time, the main cause of death remains relapse of malignant disease. [51]

Complications of HSCT

Infection

Following HSCT, the immune system takes several weeks to recover; the rapidity of recovery is dependent on the type of transplant, source of stem cells, age of the recipient and donor, myeloablative regimen, presence of GVHD and degree of immunosuppression. [52] The period of engraftment is divided into three phases subjecting the transplant recipient to risks of different infections, with most ICU admissions arising during the pre-engraftment phase [53] :

Pre-engraftment (<30 days). Recipients are susceptible to bacterial infections due to neutropenia. The use of novel broad-spectrum antibiotics with comprehensive gram-negative coverage has resulted in gram-positive organisms (*Staphylococcus* spp, *Streptococcus*, *Enterococcus*) being largely responsible for bacteraemias following HSCT.

Early post-engraftment (30–100 days). Cell-mediated immunity remains impaired and the recipient is at risk of viral and fungal infections such as Cytomegalovirus (CMV), *Pneumocystis jirovecii* and *Aspergillus* spp.

Late post-engraftment (>100 days). Impaired reticuloendothelial, cell-mediated and humoral function mean recipients are at risk of mycobacterial and viral infections.

Pneumocystis jirovecii pneumonia is less common with the effective use of trimethoprim-sulphamethoxazole prophylaxis. Fungal infections remain a threat with *Aspergillus* spp and *Candida* spp predominating. The routine use of azole prophylaxis has reduced the number of *Candida albicans* infections but resulted in the emergence of azole-resistant species.

Viral Infections

Viral infections may arise due to reactivation of latent viruses or acute infection. Patients may be managed with either prophylactic or pre-emptive anti-viral strategies whereby treatment is started in response to asymptomatic viraemia to prevent subclinical infection progressing to life-threatening disease. Severe infections may require a reduction in immunosuppression to promote T-cell immune reconstitution. Resistance is uncommon in the anti-viral naïve patient population, and testing is not routinely performed.

CMV

Uncontrolled CMV infection can affect the lungs, heart, gastrointestinal tract, liver, retina and CNS and remains an important cause of mortality. In the absence of a threshold viral count for initiating treatment, risk factors such as presence of GVHD, use of corticosteroids ≥1 mg/kg, lymphopenia and rapid viral load doubling times are considered. [54] Pre-emptive treatment or treatment of breakthrough viraemia despite prophylaxis should be aggressively managed with either ganciclovir or valganciclovir. Both agents are myelotoxic and bone marrow support with granulocyte-colony stimulating factor (G-CSF) may be required. Alternative agents such as foscarnet or cidofovir may be considered to reduce the risk of myelosuppression; however, they carry a greater risk of renal impairment. Prophylactic agents such as letermovir should be discontinued when alternative anti-viral therapies are initiated. Leukocyte depletion has effectively reduced the risk of transfusion-associated CMV within the UK. CMV has a doubling time of one to two days in untreated patients, and therapy should not be changed within the first two weeks due to perceived lack of effect as reflected by an increase in viral load. Progression of disease despite treatment should prompt testing for drug resistance, and escalating drug dose or switching anti-viral agents. Intraocular therapy may be required for retinal disease when present.

Adenovirus

Adenoviral infection following allogenic HSCT can result in severe haemorrhagic enteritis, cystitis, encephalitis, pneumonia, hepatitis, nephritis, myocarditis and multi-organ failure with a mortality approaching 50%. [55] Cidofovir competitively inhibits the viral DNA polymerase and is typically used to prevent worsening viraemia. It is a virostatic agent, however, with poor cellular uptake and T-cell immune reconstitution is required to clear the infection. Due to dose-limiting nephrotoxicity cidofovir is not used prophylactically. This nephrotoxicity may be mitigated by hyperhydration, administration of 1 mg/kg three times per week and co-administration of probenecid. [56]

BK-Polyomavirus (BKPyV)

Early onset haemorrhagic cystitis (HC) may occur during the conditioning phase of HSCT due to direct cytotoxic effects of chemotherapy or radiotherapy on the urothelial mucosa. Late-onset HC typically occurs during the pre-engraftment phase or within the first 6-months following HSCT due to uncontrolled replication of the BKPyV. A diagnosis of

BKPyV-HC consists of symptoms and signs of cystitis, macroscopic haematuria with or without clots and BKPyV viruria.[57] Treatment consists of supportive management with hyperhydration, bladder irrigation and anti-viral agents such as cidofovir.

Epstein-barr virus (EBV)

Post-transplant lymphoproliferative disorder (PTLD) is almost exclusively due to EBV infection in post-HSCT patients resulting in uncontrolled proliferation of lymphoid or plasmocytic cells. Patients typically present with fever, malaise, lymphadenopathy, an infectious-mononuclear syndrome or local symptoms related to extra-nodal disease within the chest, abdomen, CNS, bones and skin. B-cell depletion with rituximab monotherapy is first-line therapy and has reduced mortality from >80%, to approximately 30%.[58]

Severe acute respiratory syndrome coronavirus (Sars-CoV-2)

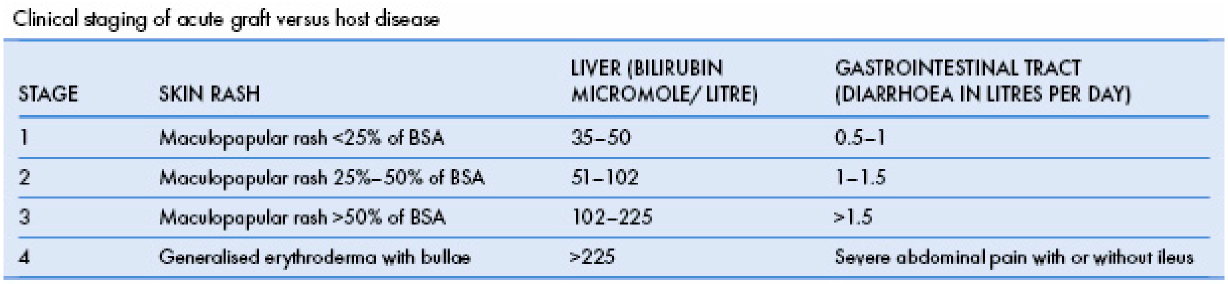
Symptoms of infection with Sars-CoV-2 resulting in the coronavirus disease pandemic (COVID-19) are similar between immunocompetent and immunocompromised patients, with the latter group having a greater severity of disease, a prolonged viral phase of infection and poorer outcomes with untreated mortality exceeding 40%.[59] Due to the relatively longer viral phase of infection, patients may derive greater benefit than the general population from anti-viral agents such as remdesivir.[60], [61] The immunogenic response to vaccination is variable and dependent on factors such as age, underlying malignancy, remission status and recent SACT. Irrespective of malignancy, the antibody titers following immunisation remain lower than healthy controls, with subsequent reductions in antibody titer over time. Patients should be considered as vaccine-naïve irrespective of following HSCT and require repeat vaccination.[62]

Graft versus host disease (GVHD)

GVHD is an inflammatory disorder thought to arise due to non-infectious (predominantly cytotoxic chemotherapy) and infectious tissue damage resulting in the release of damage-associated and pathogen-associated molecular patterns which promote a dysregulated immune response, and donor T-cell targeting of the host tissue. This response is heightened by greater HLA-mismatch.[63] Acute GVHD occurs in up to 50% of cases, with chronic GVHD manifesting in 30%–70% of cases.[64] Approximately 20% of deaths following transplantation are attributed to GVHD.[65]

Acute GVHD classically presents 7–28 days post-transplant with a maculopapular skin rash, diarrhoea and/or intra-hepatic cholestasis. The diagnosis is confirmed by histological analysis and disease severity is defined by the extent and number of organs affected (See Tables 114.3 and 114.4).[66] Immunosuppression with steroids and steroid-sparing agents such as tacrolimus and cyclosporine form the cornerstone of management for acute GVHD. Topical steroids are used for mild skin and gut disease, whilst systemic steroids are reserved for grade II–IV disease.[67] Gastrointestinal involvement with secretory diarrhoea may necessitate the need for parenteral nutrition and octreotide. The degree of acute GVHD has been shown to be predictive of 100-day survival.[68]

Table 114.3



Clinical staging of acute graft versus host disease

STAGE	SKIN RASH	LIVER (BILIRUBIN MICROMOLE/ LITRE)	GASTROINTESTINAL TRACT (DIARRHOEA IN LITRES PER DAY)
1	Maculopapular rash <25% of BSA	35–50	0.5–1
2	Maculopapular rash 25%–50% of BSA	51–102	1–1.5
3	Maculopapular rash >50% of BSA	102–225	>1.5
4	Generalised erythroderma with bullae	>225	Severe abdominal pain with or without ileus

---

BSA , Body surface area.

Table 114.4

Grading of acute graft versus host disease

GRADE	CLINICAL MANIFESTATIONS
I	Stage 1–2 skin, no gut or liver involvement
II	Stage 3 skin, stage 1 gut or stage 1 liver
III	Stage 3 skin, stage 2–4 gut or stage 2–3 liver
IV	Stage 4 skin, stage 4 gut or liver

Chronic GvHD mimics collagen vascular disorders and systemic sclerosis with symptoms occurring ≥100 days post-transplant. In addition to cutaneous, ocular and secretory gland dysfunction, pulmonary (bronchiolitis obliterans) and neuromuscular (polyneuropathy, polymyositis and myasthenia gravis) involvement and liver dysfunction (hepatitis, cirrhosis) may also occur. Treatment is difficult and disease progression can be limited by increasing immunosuppression (with a consequent risk of infection). Second-line agents such as mycophenolate mofetil and ruxolitinib are considered if there is a failure to control symptoms in addition to more advanced therapies such as extracorporeal phototherapy for both acute and chronic GVHD. [69], [70]

Graft Failure

Graft failure occurs in 5%–11% of patients following allogeneic HSCT, resulting in ongoing transfusion dependence and persistent cytopenia of ≥2 cell lineages for more than six weeks after transplantation. [71], [72] Causes of graft failure include inadequate stem cell infusion, infection and acute GVHD. Graft failure is associated with an increased risk of infection and mortality. Management consists of augmentation with granulocyte stimulating factor (G-CSF), donor lymphocyte infusion or repeat transplantation.

Diffuse Alveolar Haemorrhage (DAH)

DAH occurs within 30 days of transplant due to pulmonary endothelial damage during conditioning chemotherapy and radiotherapy. It is characterised by rapidly progressive respiratory failure with dyspnoea, anaemia, hypoxaemia, fever and diffuse infiltrates on CXR. Frank haemoptysis is rare. Bronchoalveolar lavage (BAL) demonstrates bloody aspirates with ≥20% haemosiderin-laden macrophages despite serial lavage. [73] Despite treatment with corticosteroids, mortality remains high. [74]

Engraftment Syndrome

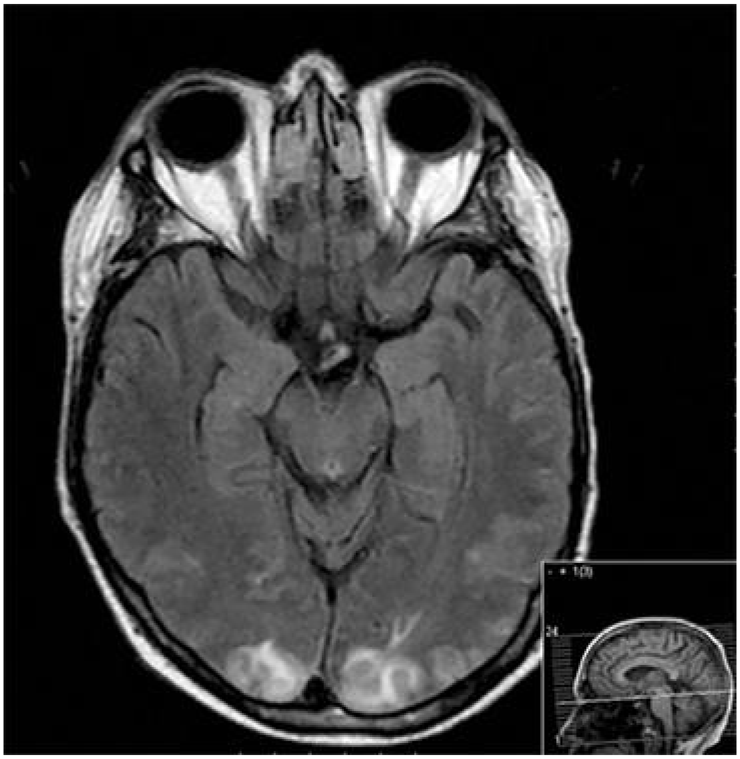
Engraftment syndrome typically presents within 4 days of neutrophil recovery following HSCT with fever, erythematous rash and non-cardiogenic pulmonary oedema. Other features include abnormal liver function tests, transient encephalopathy and multi-organ failure. Use of G-CSF increases the prevalence of this syndrome and should it occur, G-CSF should be discontinued. CT scans of the chest typically demonstrate bilateral ground-glass opacification. Management is supportive and cases that do not resolve spontaneously should be started on corticosteroids. [75]

Veno-Occlusive Disease (VOD)

VOD, also known as sinusoidal obstruction syndrome, presents as a triad of painful hepatomegaly, jaundice and ascites 3 weeks following HSCT. Other features include weight gain, encephalopathy, bleeding and hepato-renal syndrome. Doppler ultrasound demonstrates reduced or reversed portal venous blood flow, and a liver biopsy may be performed to confirm the diagnosis. Treatment is with defibrotide, a polydeoxyribonucleotide with anti-thrombotic, anti-inflammatory and fibrinolytic activity. [76] Severe VOD has a mortality of 85%.

Posterior Reversible Encephalopathy Syndrome (PRES)

PRES is a small vessel microangiopathy of the cerebral vasculature characterised by confusion, headache, visual loss and seizures. T2 weighted MRI characteristically shows diffuse subcortical hyper-intensity involving the parieto-occipital white matter. Hypertension if present should be aggressively controlled, and medications associated with PRES such as tacrolimus, ciclosporin and mycophenolate mofetil should be stopped (Fig. 114.1). [77]



The axial brain M R I scan shows bilateral orbits at the top of the scan with surrounding soft tissue and extraocular muscles. The temporal lobes are visible laterally, and the brainstem is centrally located. Posterior regions reveal portions of the cerebellum. Structural brain anatomy appears in grayscale with soft tissue contrast. A sagittal reference view is inset in the lower right corner, exhibiting the scan plane location across the cerebrum and brainstem.

FIG. 114.1 Magnetic resonance imaging scan of the brain (T2 with flair) shows high signal bilaterally involving the occipital lobes in keeping with posterior reversible encephalopathy syndrome.

Transplant-associated thrombotic microangiopathy (*TTMA*)

TTMA arises due to microvascular thrombi deposition due to excess complement deposition and resultant endothelial cell separation. The kidney is often the primary site of microangiopathy and patients present with hypertension and proteinuria. Elevated serum creatinine and the development of AKI and renal failure are late features and reflect extensive microthrombi deposition. Gastrointestinal involvement with abdominal pain and diarrhoea is often difficult to distinguish from GVHD, and neurological symptoms are an unfavourable predictor of mortality. The blood film should demonstrate schistocytes alongside a positive haemolysis screen. ADAMTS13 levels should be sent to differentiate TTMA from thrombotic thrombocytopenic purpura. Treatment with Eculizumab to block the terminal complement pathway and prevent formation of the membrane attack complex has surpassed therapy with plasma exchange or rituximab.[78]

Patients with Haematological Malignancy in the ICU

Patients with haematological malignancies develop critical illness either due to their underlying cancer or cancer-related treatments such as chemotherapy, radiotherapy or HSCT. Outlined below are some common reasons for ICU admission.

Neutropaenia and Neutropaenic Sepsis

Neutropenia is defined as an absolute neutrophil count (ANC) of $<1.5 \times 10^{9}$/L. Severe neutropaenia is defined as an ANC $<0.5 \times 10^{9}$/L. Fever is common in patients with haematological malignancies and differentiating infectious from non-infectious causes of fever is notoriously difficult. Severe sepsis and septic shock in patients with haematological malignancies have reported mortality of 36%–45%.[79, 80] Culture specimens should be sent on admission, including blood cultures from each lumen of existing central venous catheters.

First-line antibiotic treatment is with an anti-pseudomonal ß-lactam agent, such as cefepime, a carbapenem (meropenem or imipenem-cilastatin) or piperacillin-tazobactam. Aminoglycosides, fluoroquinolones and/or vancomycin should be added to the initial regimen in the event of septic shock or if antibiotic resistance is suspected.[81] Vancomycin (or another agent active against resistant gram-positive cocci) should also be added if there is a suspected catheter-related infection, soft-tissue infection or pneumonia. Empirical antifungal therapy should be considered for patients with persistent or recurrent fever. The need for anti-viral agents or treatment-dose trimethoprim-sulphamethoxazole should be evaluated.

G-CSF is often used to promote neutrophil recovery in patients with profound neutropenia. Blood cell counts should be obtained daily, and the G-CSF should be discontinued when the white cell count is $>1.0 \times 10^9$/L or the ANC $>0.5 \times 10^9$/L. Side effects of G-CSF include rash, injection site reaction, bone pain and flu-like symptoms. Finally, environmental precautions should be taken when managing neutropenic patients with meticulous hand hygiene, full barrier precautions and protective patient isolation.[82, 83]

Neutropenic Enterocolitis

Patients typically present with abdominal pain, fever and diarrhoea after chemotherapy (especially cytosine arabinoside, vinca alkaloids and doxorubicin). It is caused by a combination of chemotherapy-induced colonic mucosal wall damage, thrombocytopaenia-related gastrointestinal bleeding and colonisation of the bowel by pathogenic bacteria. Complications include bacteraemia, gastrointestinal bleeding and perforation (5%–10%). Abdominal CT scanning may demonstrate pneumoperitoneum or colonic pneumatosis indicating colonic damage with imminent perforation. Management is conservative with bowel rest, parenteral nutrition and antibiotics that target enteric gram-negative and anaerobic organisms, including *Clostridium difficile* . Surgery may be required in patients with uncontrolled sepsis, bowel perforation or life-threatening gastrointestinal bleeding.

Respiratory Failure

Acute respiratory failure is the most common cause of ICU admission in patients with haematological malignancies. The reason for respiratory failure is often infection, although other non-infectious causes should be considered (see Table 114.5). Lung protective ventilation strategies, early use of non-invasive ventilation and BAL to aid diagnosis have all contributed to improvements in outcome.[84], [85] The diagnostic yield of BAL is ≥45% and has been shown to improve short-term survival without an increase in adverse events such as the requirement for mechanical ventilation.[86], [87] Routine transbronchial biopsy is not recommended.

Table 114.5

HSCT , Haematopoietic stem cell transplant, *spp* , species.

Acute Oncological Emergencies

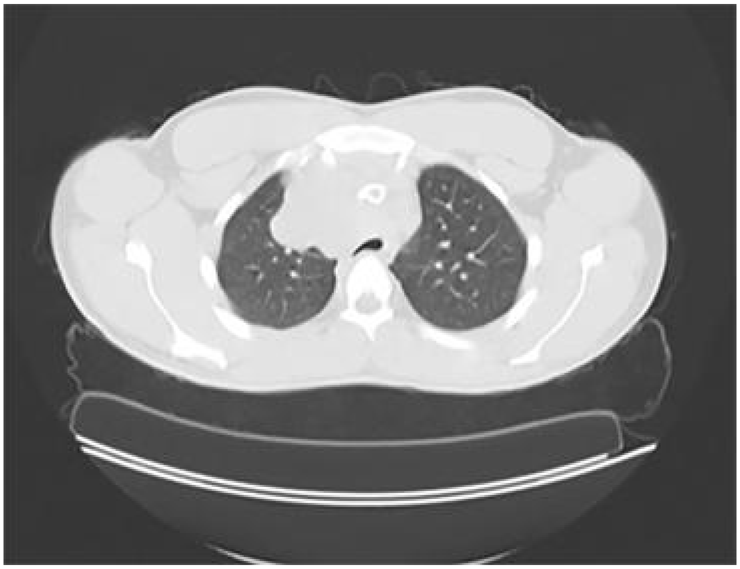
A small number of patients are admitted directly to ICU with complications of their haematological malignancy requiring urgent chemotherapy and/or radiotherapy. These include:

1. *CNS involvement.* CNS involvement resulting in focal deficits, seizures, alteration of consciousness or high spinal cord compression is an indication for urgent chemotherapy and/or radiotherapy.
2. *Mediastinal masses and pericardial disease.* Bulky mediastinal masses with compression of the trachea, main bronchi or major vessels are often due to NHLs and require urgent chemotherapy, radiotherapy or endobronchial stents to relieve the compression (Fig. 114.2).
3. *Disseminated intravascular coagulation.* DIC may be a presenting feature of APML or develop due to severe infection. The cornerstone of management for DIC is to treat the underlying condition and supportive blood product transfusion.
4. *Tumour lysis syndrome.* Tumour lysis syndrome is caused by the rapid lysis of tumour cells following chemotherapy leading to the release of excessive quantities of intracellular contents into the systemic circulation. The metabolic disturbance is characterised by hyperkalaemia, hyperphosphataemia, hypocalcaemia,

hyperuricaemia which may lead to acute kidney injury and cardiac arrhythmias. Furthermore, purine breakdown by xanthine oxidase results in the formation of xanthine and uric acid which may result in nephrotoxicity. TLS is commonly associated with acute leukaemias and high-grade lymphomas, and thus close monitoring of electrolytes is required when starting chemotherapy in patients with a high tumour burden. In addition to aggressive fluid hydration, allopurinol, febuxostat or rasburicase (a recombinant urate oxidase enzyme) are used prophylactically to prevent this accumulation of toxic metabolites. [88] Renal replacement therapy may be required in severe cases. Urinary alkalinisation with sodium bicarbonate may precipitate calcium-phosphate and xanthine within the renal tubules, worsening acute kidney injury and is not recommended.

5. *Hyperviscosity syndromes.* Hyperviscosity syndromes occur with multiple myeloma, leukaemia and Waldenstrom's macroglobinaemia. Clinical manifestations include headaches, coma, seizures, visual impairment, retinal haemorrhages and mucosal bleeding. Emergency management entails plasmapheresis to reduce blood viscosity followed by urgent chemotherapy to reduce the number of circulating monoclonal immunoglobulins. [89]
6. *Leukostasis.* Leukostasis is defined as a total leukocyte count of $>100 \times 10^9$/L and may be seen during leukaemic blast crisis. Leukocytes occlude the vasculature, decreasing tissue perfusion and result in limb ischaemia, myocardial infarction, renal failure, respiratory failure and neurological dysfunction. [90] Urgent SACT or leukapheresis is required to reduce mortality due to cerebrovascular accident or concurrent DIC and TLS.
7. *Haemophagocytic lymphohistiocytosis (HLH)* . HLH also known as macrophage activation syndrome, is a recognised presentation of NHL, HL and complication of CART-therapy. [91], [92] Typical manifestations of HLH are fever, hepatosplenomegaly and cytopenias. Severe cases may present with a sepsis-like picture and multi-organ failure. Laboratory finding include low erythrocyte and leukocyte counts, hypoalbuminaemia, hypertriglyceridaemia,

hypofibrinogenaemia and hyperferritinaemia (>500 μg/L). [93] Marked hyperferittinaemia ≥10,000 μg/L is sensitive and specific for HLH paediatric cohorts but is a non-specific finding in adults and may reflect renal failure, hepatocellular injury or infection. [94] Typical bone marrow findings include activated macrophages phagocytosing platelets, erythrocytes and leukocytes. Steroids and etoposide are the mainstays of treatment in malignancy-associated HLH prior to induction chemotherapy. [95]



The axial C T scan of the chest is at the level of the upper thorax. Both lungs are partially inflated with visible pulmonary markings. The mediastinum is centrally located and includes the trachea, major blood vessels, and surrounding soft tissue structures. The bony contours of the ribs, clavicles, and thoracic vertebrae are seen peripherally. Subcutaneous fat and muscle layers encircle the thoracic cavity.

FIG. 114.2 Computed tomography scan of the chest showing bulky infiltrative mass (non-Hodgkin lymphomas) extending from the anterior mediastinum to the right paratracheal space with tracheal compression.

Chemotherapy in ICU

In some circumstances starting chemotherapy in the ICU, even when infection or organ failure is present, may be appropriate to limit disease progression that results in death. Modification of chemotherapeutic regimens may be required to limit organ toxicity and the duration of neutropenia. In carefully selected cases of patients given chemotherapy in the ICU published outcomes have been reasonable with an in-hospital mortality of 43%.[96] In fact, the administration of chemotherapy, in the ICU setting or within the last 3 weeks prior to ICU admission, does not appear to be associated with an increased risk of death.[97]

Predictors of Mortality in Patients with Haematological Cancer

Several studies have looked at predictors of mortality to help identify those patients with haematological malignancy most likely to benefit from ICU care. Factors such as neutropenia, autologous transplant, underlying haematological diagnosis or the presence of septic shock are no longer indicative of poor outcome.[98–101] Advanced age, multi-organ failure, mechanical ventilation, vasopressor requirement, renal replacement therapy, GVHD, elevated serum lactate on admission and allogeneic transplantation continue to be associated with poorer outcomes.[49, 101–106] Acute Physiology and Chronic Health Evaluation (APACHE) II scores and Simplified Acute Physiology Score (SAPS) II scores may underestimate mortality in patients with haematological malignancies, however, they remain useful in cases of HSCT.[104, 105, 107, 108]

Outcomes of Patients with Haematological Malignancy Admitted to the ICU

Previous studies have reported that patients with haematological malignancies who require intensive care often face a poor prognosis with in-hospital mortality rates of >80% reported in the mid-1990s.[109] Due to improvements in chemotherapeutic regimes with reduced organ toxicity, better patient selection, increased use of non-invasive ventilation and general improvements in ICU, mortality rates are now 40%–50%.[2, 101, 105, 109] A joint approach between intensivists and haematologists in the delivery of patient care, early ICU admission of patients at risk of developing organ failure and effective triaging of patients who are unlikely to benefit from ICU care are also important contributory factors.[110, 111]

This trend towards lower mortality provides a strong argument against the traditionally held negative perception of patients with haematological malignancy admitted to the ICU.

Organ donation

Helen Ingrid Opdam and Daniel John Roberton Harvey

Introduction

Organ donation is an important consideration for many patients approaching end-of-life in the intensive care unit (ICU). The gift of organ donation saves and transforms the lives of thousands of people globally via transplantation. [1] It is usually the best, and often only, treatment for end-stage organ failure. Despite many organisational and technological improvements in the organ donation process in recent years, opportunities to donate remain relatively rare and only approximately 2% of people dying in hospital may be suitable depending on case-mix. [2, 3] This means that every person who could possibly donate organs at the end-of-life must be recognised, as missed opportunities will worsen the burden of ongoing dialysis and contribute to the deaths of patients in need of transplantation. Identifying and offering the opportunity to donate is also important for respecting the decision of individuals and families who wish to donate.

The vast majority of organs for transplantation are donated after death and, whilst living donation is an important contribution towards organs for transplantation in many countries, this donation pathway is not relevant to intensive care medicine and will not be discussed further here. [4]

Donation is an altruistic act and the success of organ donation and transplantation programmes is reliant on public trust. This requires fairness and equity in access to transplantation and donation processes that are transparent, ethical and undertaken to an exemplary medical standard. A crucial ethical concept, the ‘dead donor rule’, encapsulates a key moral principle that organ donation must not cause the death of the donor and can only take place after a person has died. Death must be diagnosed according to current medical standards and local laws using either circulatory or neurological criteria (see Chapter 14).

Nomenclature and Definitions

The nomenclature of donation has changed over time and there continues to be a range of terminology around the world to describe aspects of the donation process. Many changes aim to improve the accuracy, clarity and appropriateness of language given the sensitivity of donation. Language that is confusing, lacking compassion and ill-considered should be avoided. By biasing the perception of organ donation in the minds of professionals, patients and families or by causing unnecessary concern about the ethics or practicalities of organ donation, such language may reduce the opportunities for subsequent donation and cost lives.

An obvious example is the use of the word ‘harvest’, which is now regarded as offensive by the majority of clinicians and donor families, with terms such as the organ ‘donation operation’, ‘retrieval’ or ‘recovery’ preferred. The terms donation after neurological determination of death (DNDD) and donation after circulatory determination of death (DCDD) have replaced less accurate terms. Table 115.1 provides examples of contemporary terminology that has superseded less desirable terminology.

Table 115.1

Terminology used in deceased donation

Preferred term	Inappropriate or less accurate term
Organ donation operation/Organ retrieval/Organ recovery	Organ harvest/Organ procurement
Deceased donor	Cadaveric donor
Ventilator	Breathing machine
Artificial support	Life support
‘Offer’/‘Discuss/Approach’ donation	‘Request’ donation
‘Decline’ donation	‘Refuse’/‘Object to’ donation
Neurological death	Brain/Brainstem death
Donation after neurological determination of death (DNDD)	Heart-beating donation
Circulatory death	Cardiac death
Donation after Circulatory Determination of Death (DCDD)	Donation after Cardiac Death (DCD)/Non-heart-beating donation (NHBD)
Donated organs and tissues	Body parts

DCDD has been categorised by the Maastricht criteria, which emphasises the degree of control over the preparations for, and timing of, death and organ retrieval. The original 1995 classification has since been revised and a modified Maastricht classification version is provided in Table 115.2 . [5]

Table 115.2

Modified Maastricht classification for DCDD

Category 1	Out of hospital cardiac arrest with unsuccessful resuscitation – dead on arrival at hospital	Uncontrolled
Category 2	In hospital cardiac arrest (unexpected) with unsuccessful resuscitation – in emergency department, ICU or ward	Uncontrolled
Category 3	Expected cardiac arrest after withdrawal of supportive treatment – in ICU or operating theatre	Controlled
Category 4	Cardiac arrest following neurological determination of death, unexpected or expected – in ICU or operating theatre	Uncontrolled if unexpected Controlled if after planned withdrawal of supportive treatment e.g. family wish to be present at this time
Category 5	Medically assisted death – in ICU, ward or operating theatre	Controlled

ICU , intensive care unit.

Most DCDD in ICU is controlled and occurs according to Maastricht category 3. [4, 6] Uncontrolled DCDD is logistically challenging and the limited programmes that exist are more relevant to emergency departments (EDs) than ICUs. Donations following medically assisted dying are increasing in countries that have introduced relevant legislation,[7] and may or may not involve intensive care clinicians depending on local procedures and practices.[8] Discussion of DCDD in this chapter will be restricted to controlled DCDD following withdrawal of life-sustaining treatment (WLST), which is the type of DCDD most relevant to the practice of intensive care. We refer readers interested in other forms of DCDD to comprehensive reviews in the literature.[9]

Ethical and Legal Framework

Ethical decision making in organ donation in most Western countries, and certainly in Australia and the UK, is based on the four pillars of beneficence, non-maleficence, justice and autonomy. As with many decisions, a balancing is required when these principles might be in potential conflict. Beauchamp and Childress authored perhaps the preeminent text, which is highly recommended for in-depth review, and a practical approach outlined by the authors.[10]

Ethical decision making in the ICU is a primary duty of the intensive care team and can be complex and challenging. It is an undoubted cause of emotional burden on ICU staff[11], [12] and may be a cause of burnout especially where real or perceived conflict exists within individuals, within clinical teams or between clinical teams and patient families or advocates.[13], [14]

The primary ethical decision made by clinical teams is taken prior to the decision to donate, and that is a planned change in the goals of care from treatment targeted at recovery and survival to the palliation of symptoms and WLST. Such decisions are often shared with families acting as patient advocates and representatives, although in the UK and Australia, the relevant medical law and ethics places ultimate responsibility for decision making for incapacitated adults with the medical team. Although there might be various reasons for a change in the goals of treatment, often it is the realisation that a catastrophic brain injury or other devastating illness has occurred, and with it the loss of reasonable hope and expectation of recovery to a functional state that the patient would find acceptable. The prior expressed views, opinions, wishes and beliefs of the patient would of course be crucial in such decisions, however, it is often conveyed by family rather than being formally documented. Globally there are a range of medical ethical models employed, and not all of these recognise the decision to WLST in such circumstances as being one that rests with medical teams and families.

Decision making is often less challenging where a diagnosis of death by neurological criteria can be made, in which case a prognosis with an inevitable if negligible degree of uncertainty is replaced by the certainty that recovery is impossible. Withdrawal of ventilation is not only sanctioned but often mandated, in many clinical, legal and ethical contexts, with or without donation.

Decisions related to organ donation may often be confused by the public, families and inexperienced staff as being co-dependent on the decision to WLST, or with performing tests of brainstem function for brain death determination, or even that a decision to WLST might be unduly influenced or even driven by a desire to donate. To avoid these perceptions, it is important that the decision to WLST is separate from a decision to donate. [15] It is also advocated that determination of brain death be undertaken whenever it is suspected, irrespective or any potential for organ donation. [16] Decision making should focus foremost on end-of-life, whether that be to diagnose brain death, or to reach a decision to limit or withdraw treatment because of a poor prognosis. Such decisions should be led by the clinical team, considering the patient's values and preferences as documented or conveyed by the family. In general, only after death has been diagnosed and understood by the family (in the circumstance of brain death) or agreement has been reached to withdraw treatment, should the topic of donation be introduced. [17]

In both the UK and Australia, the legal basis for authorisation or consent for organ donation is provided in Human Tissue Acts or similar legislation, and these Acts also stipulate the requirements for death determination and professional obligations for maintaining anonymity of the donor and transplant recipients. Many countries will have detailed legislative and professional codes of practise that defend core ethical principles in organ donation such as the dead donor rule and requirements for consent. [17], [18] Consent or authorisation for donation is requisite before donation can proceed. First-person consent is possible where the patient had previously made clear their donation decision, or in the rare situation of a conscious, competent patient who is requesting cessation of supportive treatment and provision of end-of-life care (e.g. high spinal cord injury ventilator dependent patient). The former instance is supported in many countries through donor registries. Where the patient's views on donation are unknown, families are usually consulted to make a substituted decision on their behalf.

There is an important but subtle difference between families making a decision on what *they* wish to happen (donate or not) versus considering what *the patient would wish to happen* . A crucial component of compassionate communication, which is critical in the family approach to discussing organ donation, is to make sure this is understood by families and that the patient's values, goals and preferences are prioritised.[19] The process and context of organ donation are complex and unlikely to be appreciated by most individuals when they express wishes regarding donation, through donor registries or other means. It can be argued that, even if a person had indicated a willingness to donate, this should not be assumed to give sufficient or informed consent to any and all aspects of organ donation. Instead, a previously stated preference regarding donation can be taken as the default starting position for a detailed conversation with family.[17,18]

Family decisions are generally consistent with a person's registration status, with consent rates of 80 to 90% in both the UK and Australia for registered potential donors.[3,20] Reasons for lack of family consent in individuals registered to donate include that the person had changed their mind, that the family does not believe they would wish to donate given the process involved, and unwillingness to wait for the timeframes required to organise the donation.

In addition to individual or family consent, authorisation for donation may be required from the coroner if the death falls within the jurisdiction of the coroner. In many countries, the law also requires a specific role within the hospital of an officer who provides the final authorisation for donation and has the responsibility for ensuring that all of the legal requirements have been met, including those regarding documentation and relevant consents.

As the clinical, social and health economic benefits of transplantation are very clear, and recognising the high proportion of the population that consistently supports organ donation often does not tally with lower rates of family consent at the time of approach, there is an increasing international move toward ‘presumed consent’ also termed ‘deemed consent’ or ‘opt out’. The UK has recently moved to a deemed consent system, although has continued a register that allows individuals to indicate a willingness to donate which now also facilitates individuals being able to opt out, such that if no decision is made consent will be deemed. The system in the UK is one of ‘soft opt out’, in which even if a person did not register a decision and willingness to donate can be presumed, donation will not proceed in the face of family opposition.

Interpreting the effects of such changes in the legislative approach to donation is complex,[21] and the UK experience coincided with the COVID pandemic,[22] and it remains uncertain whether such changes will result in higher rates of consent and donation.[23,24] This is perhaps unsurprising, as the donation process and such rates depend on many other factors, including sociological, organisational, resourcing and end-of-life practices.[25] Australia continues to have an ‘explicit consent’ system, where consent from the individual or their family is required with no presumption either of willingness or objection to donation made if an individual’s wishes are not known.

Although donation decisions might be known for a particular patient, the circumstances at the time of death may mean families are unable to support their previously expressed decision. The specific reasons for this should be carefully explored by experts trained and experienced in organ donation family communication.[17] In the UK and Australia, such family decisions are currently respected. Strong ethical arguments can be made in support and opposition to this approach, and the broader impact on the societal view of donation and trust in the system are important considerations[21,26].

Even though the legal context for donation consent may be different between countries there are a number of system-wide interventions that have consistently been associated with higher organ donation and transplant rates [6], [27–29]:

- Making consideration of organ donation a routine and expected part of end-of-life care in intensive care
- Family approach to offer donations undertaken by specifically trained clinical professionals
- Coordination of organ donation activity, surgical retrieval, and transplantation across a health care system; donation and transplantation is one of the most clinically and logistically complex interventions in health care
- Supportive and enabling legislation, professional codes of conduct and guidance, and public education and promotion

Donor Identification and Referral

It is important that there are processes in place to ensure that all patients approaching end-of-life who could possibly be organ donors are identified and referred to donation services. This ensures equity of opportunity for donation, reduces the effect of possible health professionals' bias or lack of knowledge regarding various types of deceased donation and suitability, and maximises donation and transplantation outcomes. [30]

Many jurisdictions have introduced 'clinical triggers' in ICUs and EDs, which are criteria to prompt the timely and consistent notification of such patients to external donation agencies or donation staff embedded within hospitals. In some countries, this is mandated in law (mandatory referral). Common clinical trigger referral criteria include patients with catastrophic brain injuries and those for whom there will be WLST that is expected to lead to the circulatory determination of death. [29] It is important that the referral occurs sufficiently early and prior to any plan to limit or withdraw treatment being agreed by the family. [17]

Early referral has many advantages, including a timely assessment of the feasibility and medical suitability for donation. Advice that either excludes donation or indicates that donation is feasible, may reduce delays for both the patient's family and the ICU. It provides an opportunity for advice, if needed, regarding the neurological determination of death or on physiological optimisation after the diagnosis of death. The family approach to offering donation can be planned sooner, and the attendance of donation specialist staff assured to manage the communication with the family including, when relevant, checking the patient’s donor registration status.[29] If donation is not feasible, the family can also be informed of this, which may be important for mitigating the risk of any later regret, particularly in situations where the person had registered or indicated a willingness to donate.

Intensive care specialists have a responsibility for ensuring that routine referral criteria are adhered to and that the transition to end-of-life care is undertaken in a way that preserves the opportunity for donation.[6,31] This includes ensuring that optimal physiological treatment continues, whilst communication with the family occurs in a progressive and planned manner until it is determined that donation is not possible or has been declined by either the patient or their family.

Suitability for Donation

Criteria for donor suitability have expanded over time in terms of both the circumstances in which organ donation is feasible and medical suitability requirements. This has been driven by advances in transplantation medicine leading to improved recipient survival and quality of life, even when proceeding with the transplantation of non-ideal organs.[6,32] The incidence of brain death has fallen in many developed countries whilst the practice of DCDD has increased, driven by the huge unmet need for organ transplants and to fulfil the desire of individuals and families wishing to donate.[28,33]

Medical suitability criteria have broadened, including age limits (young and old), acceptable co-morbidities, and other conditions that may pose a small but increased risk of disease transmission to recipients. There are very few absolute medical exclusions to organ donation with the main contraindication being metastatic cancer. Persons with a history of cancer should not be automatically excluded and those with localised cancers or who have had a long disease-free interval since treatment may be suitable donors. Those with risk factors for hepatitis B, hepatitis C and human immunodeficiency virus (HIV), such as non-medical injecting drug use or men who have sex with men, may also be suitable organ donors. The availability of effective direct-acting antiviral therapies has further broadened the acceptability of donors with current or an increased risk of hepatitis C infection, and HIV is also no longer an exclusion.[34,35] Hypertension, diabetes mellitus, smoking and heavy alcohol consumption do not preclude organ donation, nor does older age with individuals in their late seventies or early eighties sometimes being suitable kidney and/or liver donors.

Identifying patients who may be suitable for DCDD can be difficult, as they include not only severely brain injured (but not fulfilling criteria for the diagnosis of neurological death) individuals but also patients with terminal cardiac, respiratory or liver failure and those with advanced neuromuscular conditions. Predicting time to death after WLST is imperfect, with it accepted that a proportion of patients planned for DCDD will not die in the timeframe that allows for successful donation and transplantation.[36,37] Currently, donation does not proceed due to death not occurring in the timeframe that allows for donation in 30% and 50% of individuals in Australia and the UK, respectively, who have WLST in the setting of planned DCDD.[20,38]

Transplant outcomes for the kidney and lungs are similar for donation after neurological and circulatory determination of death, although there is a higher frequency of delayed kidney graft function in DCDD.[39,40] Liver outcomes in DCDD are inferior as compared with DNDD, due to the vulnerability of the liver to warm ischaemic injury resulting in higher rates of primary non-function and ischaemic cholangiopathy, although the increasing use of machine perfusion technologies is improving graft and recipient outcomes and expanding liver utilisation in the DCDD setting.[41] Heart transplantation in the setting of DCDD has expanded in recent years and requires the use of machine perfusion due to the extreme vulnerability of the heart to warm ischaemic injury. A recent multi-centre United States study found transplant recipient survival to be equivalent for those receiving hearts obtained from DCDD candidates with the use of ex situ normothermic perfusion compared with those from DNDD donors using standard preservation protocols.[42] New in situ and ex situ machine perfusion technologies have the potential to greatly expand donor suitability, organ utilisation and recipient survival, particularly in DCDD (see under machine perfusion technologies).

Given these factors, it is difficult for the ICU clinical team to be certain of donor suitability, both in terms of whether DCDD is feasible and whether medical suitability criteria are likely to be fulfilled. Medical suitability is far from an absolute concept and may also be influenced by the urgency of the needs of individuals awaiting transplantation at any point in time. The possibility of organ and tissue donation should therefore be considered in all patients approaching end-of-life with routine referral facilitating assessment and guidance from donation specialist staff who have the requisite knowledge and access to other relevant information.

Supportive Treatment in Potential Donors

Patients approaching end-of-life who are potential donors should continue to receive standard intensive care in a manner similar to that provided to all critically ill patients, whilst conversations and decisions which may change the goals of care are pending. This is important in preserving the opportunity for donation and optimising donation and organ transplant outcomes, and also in maintaining trust and transparency in the healthcare system which may be especially relevant in communities with a history of health inequalities. [43]

For patients with a devastating brain injury, once it becomes clear that survival with an outcome consistent with what the individual would find acceptable is not possible, it is appropriate to discontinue neurological therapies including those aimed at controlling raised intracranial pressure, whilst continuing other supportive treatments. This is to provide time for family communication and to explore end-of-life considerations, including organ donation. This can sometimes mean increasing supportive treatments such as vasoactive agents and ensuring adequate vascular access for monitoring and drug and fluid administration until the family understands that death will occur and has made an informed and considered decision about donation. [17, 44]

Clinical decision making during this period can be challenging, with teams potentially conflicted over the rationale for ongoing invasive treatment whilst the patient's end-of-life wishes and family views on donation are unknown. Historically a default position of a narrow definition of patient's best interests often precluded the opportunity to donate, potentially a source of significant family regret.[45],[46] Some countries have recognised the potential for ethical and even legal challenges in this area, and have included explicit mention of expected interventions to support organ donation in primary legislation (Scotland) or published professional guidance to support carefully considered peri-mortem interventions for organ donation (UK,[17] Australia[38] and Spain[47]).

For patients with permanent loss of brain (-stem) function, the process of death determination using neurological criteria (brain death determination) should be undertaken according to medical standards and required pre-conditions (see Chapter 14), usually before donation is raised with family. For some patients in whom brain death is likely to develop but not yet present, the option of providing ongoing supportive treatment to allow time for brain death to occur for the purpose of facilitating donation after the neurological determination of death can be offered to the family.[16] The decision for ongoing supportive treatment should be regularly reviewed by the intensivist with the family, with agreement to discontinue support if it is no longer considered in the overall best interest of the patient.[44]

The intensive care management of potential donors, including those who develop brain death, is similar to other critically ill patients. This includes monitoring of cardio-respiratory parameters, urine output and regular blood gas analysis. Supportive treatment has recently been reviewed in the literature[48] and should aim to optimise haemodynamic status (vasopressors and/or inotropes, intravascular volume) and lung function (chest physiotherapy, suctioning, adequate positive end-expiratory pressure), correct electrolyte and metabolic abnormalities, and target euvolaemia[48] (intravenous fluids, insulin and occasionally renal replacement therapy). Blood transfusion and broad-spectrum antibiotics may be required.

The typical sequelae of brain death that include haemodynamic changes, diabetes insipidus and hypothermia should be anticipated and treated. Brainstem ischaemia and compression often result in autonomic dysfunction and haemodynamic instability, typically with marked tachycardia and hypertension. Although there is some evidence that this ‘autonomic storm’ may cause myocardial injury, it is usually brief and, if treated, the agents used should be short acting (e.g. esmolol and sodium nitroprusside). Hypotension due to peripheral vasodilatation from loss of sympathetic tone commonly, but not always, occurs in established brain death and may be exacerbated by hypovolaemia and cardiac dysfunction. Vasopressor agents such as noradrenaline are usually required, and adequate intravascular volume and cardiac output should be assured (e.g. through monitoring and, if required, inotropes).

Other common brain death sequelae include diabetes insipidus from deficiency of vasopressin (also known as anti-diuretic hormone) due to posterior pituitary dysfunction. Prompt treatment once diabetes insipidus is suspected (e.g. urine output of more than 200 ml/hour and rising sodium on serial blood gases) is important to prevent hypovolaemia, hypernatraemia and hypothermia, along with other electrolyte disturbances that are common when treatment is delayed and large amounts of low sodium intravenous fluids (e.g. 5% glucose) are administered to restore intravascular volume. Options include synthetic desmopressin (1-desamino-8-D-arginine vasopressin, DDAVP) by intravenous bolus (e.g. between 1 and 4 micrograms every 2 to 6 hours), which acts selectively on vasopressin 2 (V_2) receptors in the renal collecting tubules and/or vasopressin (arginine vasopressin, AVP) as a continuous infusion (e.g. 0.4 to 2.4 units per hour). Vasopressin also acts on V_1 receptors on vascular smooth muscle and so can also counter the vasodilator-mediated hypotension that occurs in brain death.

Hypothermia may develop from loss of hypothalamic function, vasodilation and reduced heat production from absent cerebral metabolism. It may contribute to haemodynamic instability and coagulopathy and confound the clinical determination of death using neurological criteria. Preventative and treatment measures include the use of warming blankets, warmed and humified inspired gases and warmed intravenous fluids.

The requirement for hormonal resuscitation therapy (thyroid hormone and steroids) as a consequence of anterior pituitary dysfunction is uncertain and controversial.

It has been suggested that thyroid hormone deficiency in brain death leads to mitochondrial and metabolic dysfunction contributing to reduced cardiac function and haemodynamic instability. [49] Abnormal thyroid hormone levels may occur with brain death, [50] however, this may simply constitute the sick euthyroid syndrome, commonly seen in critically ill patients. [51]

In terms of the effect of the administration of thyroid hormone to potential donors with brain death, retrospective audits and published case series tend to find a positive effect on donor haemodynamics, the number of organs retrieved or transplanted and/or graft survival. [49] These observations have led to the widespread incorporation of thyroid hormone replacement in donor support protocols, particularly if there is intended heart donation, reduced cardiac function (e.g. <45% left ventricular ejection fraction) and/or haemodynamic instability. [52] Typical protocols recommend triiodothyronine with 4 micrograms as an intravenous bolus followed by infusion of 3 micrograms per hour, or thyroxine by infusion of between 10 and 30 micrograms per hour, with or without an initial bolus (e.g. 20 micrograms). In contrast, all randomised controlled trials have reported no benefit of thyroid hormone administration in terms of donor haemodynamic stability, donor cardiac function or number of hearts transplanted, including a recent large study that included more than 800 haemodynamically unstable brain-dead heart donors, half of whom received a thyroxine infusion for more than 12 hours. [53] Concerns about the safety of donor thyroid hormone administration have been raised with risk-adjusted, retrospective registry and cohort analyses observing an association between its use and recipient heart graft dysfunction. [54,55]

There is also uncertainty over the benefit of administering steroids to potential donors with brain death. Rationales for steroid administration include treating deficiency secondary to hypothalamic-pituitary-adrenal dysfunction, to supplement a ‘functional’ or ‘relative’ adrenal insufficiency and immunomodulatory and anti-inflammatory effects.

Studies have found variable results in regard to whether patients with brain death have lower levels of cortisol or adrenocorticotropic hormone. [50,51,56] Steroid administration has been observed to improve blood pressure in patients with brain death,[57], [58] as is seen in the general critical care population in circumstances of septic and non-septic vasodilatory shock.[59]

Brain death is associated with high levels of cytokines and activation of inflammatory cascades, which may impact organ function and the likelihood of organ rejection in transplant recipients.[60–63] High-dose steroids may modulate immune function and decrease inflammation in the donor with the potential to improve recipient graft function. Intervention and manipulation of the inflammatory and immune profile of the donor is an important current research priority.

Donor administration of methylprednisolone has been associated with improved oxygenation and increased lung retrieval rates[64] and with significantly lower serum levels and liver biopsy expression of pro-inflammatory cytokines in liver recipients.[65] In kidney donors with brain death, methylprednisolone resulted in reduced inflammation and immune response seen in kidney biopsies taken at organ retrieval but had no impact on post-transplant early graft function.[66]

Current protocols include donor administration of physiological stress dose steroids for the purpose of haemodynamic support (e.g. intravenous hydrocortisone 50 mg every 6 hours) and high-dose corticosteroid administration with the intention of reducing inflammation and improving recipient graft function (e.g. methylprednisolone 1000 mg IV, 15 mg/kg IV or 250 mg IV bolus followed by an infusion at 100 mg/h). Blood for tissue typing should be collected prior to high-dose steroid administration as steroids have the potential to suppress human leukocyte antigen expression.

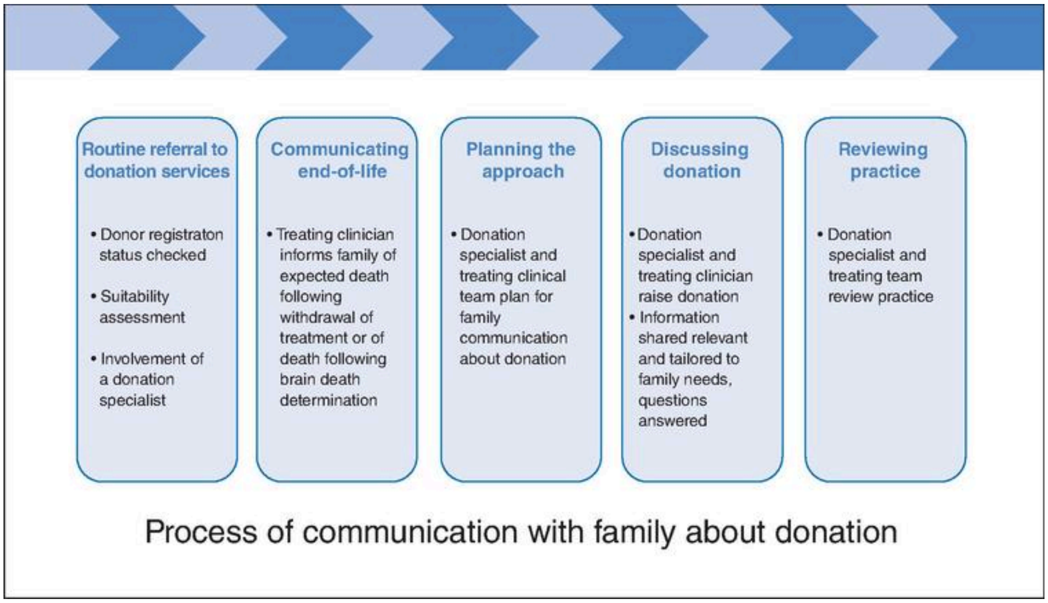
There is a need for further randomised controlled trials in the setting of donor management to clarify these questions and to provide robust evidence to maximise the number and quality of organs that might be donated.[67–70]

Family Communication and Support

The intensive care team is responsible for ensuring the family is well supported and communication occurs in a timely, clear and compassionate manner. This requires planning and collaboration with others which may include donation specialist nurses, social workers and pastoral care.

Communication should generally be graduated through a series of meetings. This might include an initial meeting conveying a possible poor prognosis, the next to explain subsequent deterioration and that death may occur, then a discussion of the likely development of brain death (if it is thought to have occurred) or that survival with an acceptable outcome is unlikely and that treatment withdrawal with a focus on comfort care is recommended and so on. Advanced education and training in organ donation, ethics and communication have been an important contributors to improved quality of organ donation practice as well as increased rates of donation and transplantation.[27, 29, 71]

Routine referral can ensure the availability of a donation specialist nurse to assist in planning how and when donation will be raised and can assist in guiding the pace and content of communication. Nurses in donation roles are sometimes invited into the earlier meetings where prognostic information and the possibility of death are conveyed in order to provide support to families, build rapport and develop an understanding of the family. It is important to avoid the premature raising of donations and to first give time for family members to understand the death or inevitability of death. When a diagnosis of brain death is likely, this concept should be explained in simple terms to the family, and consideration given to inviting family members to observe the clinical examination determining brain death. It can be useful to show and explain any brain imaging. The time of death should be clearly conveyed to families, and allowance made for grieving and spiritual or cultural practices at the end-of-life that are important to the patient and family. It is important to support junior medical and nursing staff caring for the patient throughout the death determination and organ donation process and that they understand the prognosis and death diagnosis process to aid consistency in communication with the family, and prevent moral distress or misunderstanding.[38, 72] A graphic representation of the usual steps in planning and undertaking the communication with families about donation is provided in Fig. 115.1 .



Routine referral to donation services
• Donor registraton status checked
• Suitability assessment
• Involvement of a donation specialist
Communicating end-of-life
• Treating clinician informs family of expected death following withdrawal of treatment or of death following brain death determination
Planning the approach
• Donation specialist and treating clinical team plan for family communication about donation
Discussing donation
• Donation specialist and treating clinician raise donation
• Information shared relevant and tailored to family needs, questions answered
Reviewing practice
• Donation specialist and treating team review practice

Process of communication with family about donation

The stepwise diagram presents five sequential steps in the process of communication with family about donation, each represented as a labelled box beneath a rightward pointing arrow. The first step, Routine referral to donation services, includes donor registration status check, suitability assessment, and involvement of a donation specialist. The second step, Communicating end of life, involves the treating clinician informing the family of expected death due to treatment withdrawal or brain death. The third step, Planning the approach, includes coordination between the donation specialist and clinical team to prepare for family communication. The fourth step, Discussing donation, includes the donation specialist and clinician introducing donation and sharing tailored information while addressing family questions. The fifth and final step, Reviewing practice, involves the donation specialist and clinical team reviewing the process.

FIG. 115.1 An approach to donor identification and family communication. [38]

It is important that donation is raised in a careful and planned manner and the discussion is facilitated by skilled, experienced staff who are knowledgeable about donation and can provide appropriate and accurate information. The ‘collaborative approach’ is well-established and involves a donation specialist nurse together with the treating clinician undertaking the communication with the family about the donation. Higher rates of consent are associated with family communication that involves donation specialist staff in comparison to when the treating clinician alone raises donations. [3], [20], [25], [73]

A review of the family communication undertaken by those participating is a standard part of quality improvement processes in countries with mature donation systems.

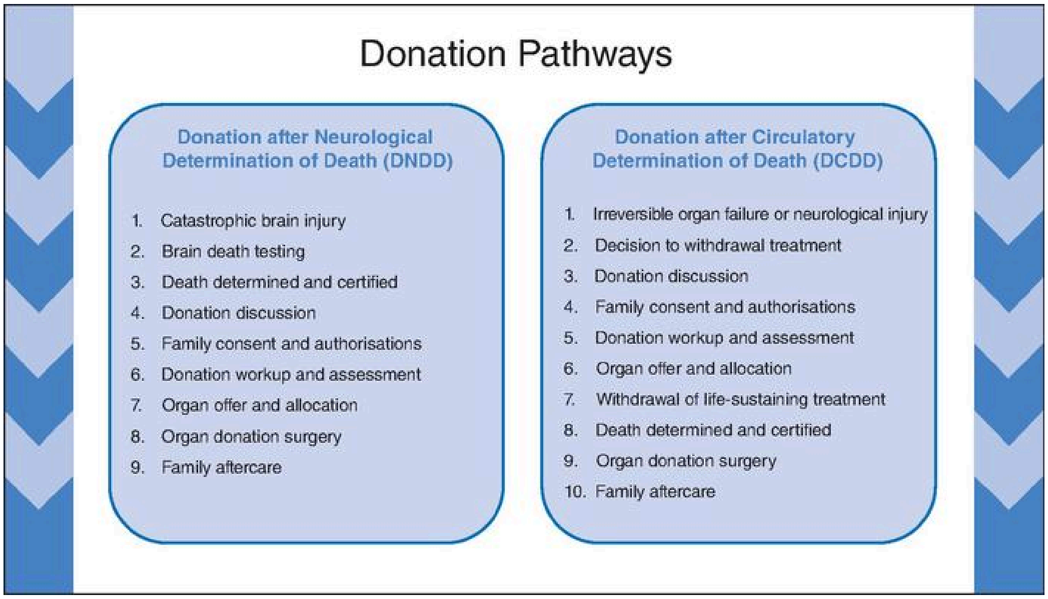
Key points in the family communication about donation:

- Communication with the family about donation should be undertaken by staff with skills, experience and knowledge about donation.
- Organ donation should not be raised prior to the family understanding the patient’s death or likely impending death. Donation is often best introduced at a separate discussion. [29]
- There should be adequate planning for family communication that covers aspects such as:
    - reviewing prior communication with the family and the details of the patient’s course in the hospital
    - how and when the topic of donation will be introduced
    - which staff will participate in the discussion and what roles they will undertake
    - which family members will be present
    - checking the patient’s donor registry status (if relevant) and how this information will be shared.

- The information shared and approach taken may vary, depending on the legal consent framework (opt in or opt out) and registration status of the patient (if relevant). It is important that sufficient time is taken for information about donation to be shared with the family, including the possibility of helping people through transplantation. The ultimate aim is that a considered decision is reached and that it be the right one for the family and centred on what the person would have wanted. Time should be taken to explore the person's values and preferences if their specific views about donation are unknown. Information should be delivered in a culturally appropriate, considered and graduated manner.
- Specific information about the donation process is generally shared later in the communication. It is important not to set up incorrect or fixed expectations, for example regarding the time period within which donation can be facilitated or the specific organs and tissues that will or will not be able to be donated.

The Donation Process and Pathways

There are some important differences in the donation process depending on whether it occurs as DNDD or DCDD. In DNDD, much of the process occurs after death has been determined, whereas in DCDD the donation assessment and organisation need to occur prior to WLST and death. Nonetheless, many of the steps are the same and, after routine referral and family communication to offer donation, they include obtaining formal consents/authorisations, undertaking a detailed medical suitability assessment, allocation of organs to recipients, organ retrieval surgery and family aftercare. A graphic representation of the usual sequence of steps for donation occurring following either the neurological or the circulatory determination of death is provided in Fig. 115.2 .



Donation Pathways

Donation after Neurological Determination of Death (DNDD)

1. Catastrophic brain injury
2. Brain death testing
3. Death determined and certified
4. Donation discussion
5. Family consent and authorisations
6. Donation workup and assessment
7. Organ offer and allocation
8. Organ donation surgery
9. Family aftercare

Donation after Circulatory Determination of Death (DCDD)

1. Irreversible organ failure or neurological injury
2. Decision to withdrawal treatment
3. Donation discussion
4. Family consent and authorisations
5. Donation workup and assessment
6. Organ offer and allocation
7. Withdrawal of life-sustaining treatment
8. Death determined and certified
9. Organ donation surgery
10. Family aftercare

The diagram presents two side-by-side columns under the heading Donation Pathways. The left column is titled Donation after Neurological Determination of Death (D N D D) and includes nine numbered steps, including catastrophic brain injury, brain death testing, death determined and certified, donation discussion, family consent and authorizations, donation workup and assessment, organ offer and allocation, organ donation surgery, and family aftercare. The right column is titled Donation after Circulatory Determination of Death (D C D D) and lists ten steps, namely irreversible organ failure or neurological injury, decision to withdraw treatment, donation discussion, family consent and authorisations, donation workup and assessment, organ offer and allocation, withdrawal of life-sustaining treatment, death determined and certified, organ donation surgery, and family aftercare.

FIG. 115.2 Donation pathways – DNDD and DCDD.

The requirements for formal consent including coronial and legal consents are covered earlier.

The donation specialist undertakes a detailed medical suitability assessment of the donor. This is critically important to the quality, safety and efficacy of organ donation for transplantation and includes further evaluation of any disease risks, which if excessive may preclude donation, and individual organ assessment for transplant suitability. The family and/or significant others are interviewed about the potential donor's health and behavioural history, the hospital medical charts are carefully reviewed and the patient's regular medical practitioner and other health providers may be contacted and records obtained. A clinical examination is performed and blood is sent for infectious disease screening and tissue typing for organ matching. Radiological and other investigations are undertaken to assess donor and organ suitability. Sometimes, additional more detailed and intensive investigations are required at the request of transplant units to assist with organ acceptance decisions and matching to specific recipients, such as computed tomography (CT), bronchoscopy and coronary angiography. Such tests are undertaken with the agreement of the family after suitable explanations and may occur after death (in DNDD) or before death (in DCDD). Local laws and protocols may restrict certain pre-mortem investigations (see later).

The donor work-up process can take many hours, particularly if there is a requirement for additional testing and/or advice from transplant specialists and other experts with respect to specific disease risks and organ suitability. The scheduling of the organ retrieval surgery is influenced by access to the operating theatre at the donor hospital and the availability of the surgical retrieval team(s) who are often remotely located through being associated with transplant unit hospitals. This can typically mean a 24-hour or longer period between the family approach to offer donation and the donation surgery.

The family is commonly provided with the choice to view the body of their relative after the donation surgery; this may be facilitated in the ICU or another suitable environment. Most donation services offer families follow-up with grief and bereavement support and general outcome information about the donation and resulting transplants.

Pre-mortem and Post-mortem Interventions

Pre-mortem (or ante-mortem) interventions are for the purpose of enabling donation and/or improving transplant outcomes. There are no agreed criteria as to what constitutes a pre-mortem intervention, and definitions may be broad, for example ‘any intervention prior to death that is for the purpose of organ donation and transplantation’ or narrower, for example ‘interventions undertaken prior to death in order to limit ischaemic injury to transplantable organs’.[5,74,75]

DCDD is not possible without undertaking some procedures and investigations prior to death to determine suitability for transplantation, facilitate organ matching with suitable recipients and maintain organ function and viability. Ante-mortem interventions are considered ethical if their potential benefits outweigh potential harms in a patient where donation would be consistent with their wishes.[17,74,76]

Local laws and policies may restrict the type of procedures that are permissible prior to death and clinicians should be familiar with these, including any consent requirements.

Post-mortem interventions in DCDD are acceptable as long as they do not breach the ‘dead donor rule’ and, where required, the appropriate consents are obtained. After death determination, which requires an absence of circulation for 5 minutes, it is important that no interventions are undertaken (e.g. mechanical ventilation and chest compressions) within a period that might inadvertently restore circulation and blood flow to the brain.[6,77] Organ donation procedures and retrieval surgery must begin with minimal delay following death to minimise warm ischaemic organ damage and resultant graft dysfunction. Lung donation requires reintubation of the trachea to prevent aspiration of gastric content, but cyclical ventilation must not take place whilst resuscitation of the donor’s heart remains possible.[78] Other techniques include flushing abdominal organs with cold preservation fluid in situ through intravascular cannulae and use of occlusion devices or external clamps to contain the flow of perfusion fluid.

Machine Perfusion Technologies

Recent advances in the application of extra-corporeal technology have the potential to revolutionise the practise of organ donation and transplantation. Broadly these technologies can be applied in two forms, either in situ in the donor or ex situ after organ retrieval.

Normothermic regional perfusion (NRP) occurs in situ in the donor after death determination using circulatory criteria and may be considered a post-mortem intervention. It entails the isolation of organ perfusion to either the abdomen (abdominal-NRP) or thorax and abdomen (thoracoabdominal-NRP) with use of an extra-corporeal circuit similar to that used to provide extra-corporeal membrane oxygenation. In thoracoabdominal-NRP, after isolation of the cerebral vessels to prevent cerebral reperfusion and establishment of NRP, mechanical ventilation of the lungs is restarted and cardiac contraction resumes enabling a functional assessment of the heart. [6] Abdominal-NRP has resulted in dramatically improved liver transplantation outcomes following DCDD with reduced primary non-function and ischaemic cholangiopathy. [41]

Current debate around the acceptability of NRP exists mostly due to the risk of re-establishment of donor cerebral perfusion either as a fundamental risk of anatomy (collateral circulation) or by misapplication of the technology, particularly with thoracoabdominal-NRP, which would violate the dead donor rule. [79] In countries where a legislated definition of death includes wording such as ‘irreversible cessation of blood in the body of the person’ (Australia) or ‘irreversible cessation of circulatory and respiratory functions’ (United States) it is arguable as to whether any form of NRP is permissible. [80], [81] The UK code of practice for the diagnosis of death is based on loss of brain functions. [82] Although there is currently extensive use of abdominal-NRP in the UK, further research to ensure lack of brain reperfusion is required before thoracoabdominal-NRP can be routinely undertaken. [83]

Ex situ perfusion involves the connection of retrieved organs to perfusion in a purpose-designed circuit, either for resuscitation or transport, with the potential for organ reconditioning and prolonged perfusion improving organ utilisation and the logistics of donation and transplantation surgery.[84, 85] Ex situ perfusion entails fewer ethical concerns than NRP, although limitations currently include the technical expertise required, speed of retrieval and associated risks and high financial cost.

Quality Improvement, Audit and Research

As the volume, impact and scale of organ donation and transplantation have increased worldwide, so too have efforts to standardise, improve and measure the quality of care. A robust consensus on legal, ethical and professional aspects of end-of-life care and organ donation practice in the ICU is a prerequisite, and is the most common reason for a lack of progress worldwide. Routine audits of hospital deaths can highlight missed opportunities for donation or lapses in expected professional approaches. Advanced multi-disciplinary training in ethics, communication skills and technical aspects of donation have also proved vital for improving the reliability of organ donation practise. National or state-wide referral systems, retrieval services and matching schemes, together with routine collection of post-transplant outcomes have all been important, although the precise impact of each will depend on context.[29]

Future of Donation and Transplantation

Much change is likely in coming years, with some advances potentially reducing the requirement for human deceased donation as it occurs today. Immune modulation has the potential to facilitate better organ and recipient matching and tolerance, with the ability to reduce or dispense with the requirement for long-term immunosuppressive, anti-rejection medication. The possibility of storing organs through novel preservation technologies will allow temporal separation of the donation and transplantation procedure and more thorough risk assessment and organ-recipient matching. Immune and genome engineering (gene editing) may herald a new age of xenotransplantation, with initial cases of heart and kidney transplants from genetically engineered pigs to humans recently reported.[86], [87] There is the potential to use stem cells and 3D printing to grow artificial organs, although currently only simple structures such as lab-grown skin using a patient's own epidermal stem cells for life-saving burns skin grafting and 3D bioprinting to recreate the external ear from a patient's own cartilage cells have reached therapeutic use.[88] More complex 'organoids' are being created using stem cells from adults or embryos with a matrix to assist growth into a 3-dimensional structure. Although some way away from growing functioning organs, organoids are being used to study how diseases develop, for in-vitro drug testing, as well as for discovering new pharmaceuticals.[89]

Summary

Historic attitudes amongst intensive care clinical staff that organ donation after death conflicted with patients' best interests have been replaced with a consensus that organ donation should be routinely considered and offered as a usual and expected part of end-of-life care. Whilst this choice will not be for everyone, where it can proceed the evidence shows a positive legacy for donors and families without risk to their medical care, and life-saving impacts for organ recipients combined with significant health economic benefits for healthcare systems. There is a need for improved research into methodologies, approaches and interventions that could be applied within the process, taking account of the impact on all those with an interest in the outcomes.

Liver and kidney transplantation

Sujit Kumar Mukherjee, Brian J. Hogan, Andrew Slack and Chris Callaghan

Liver Transplantation

Since its introduction in the 1960s, liver transplantation (LT) has revolutionised the care of patients with both end-stage, chronic liver disease and acute liver failure. An increasing burden of chronic liver disease and improving post-transplant outcomes have led to an increase in the number of transplants, with nearly 35,000 performed worldwide in 2021.[1,2] The majority of patients have a short post-operative intensive care unit (ICU) stay and 1-year survival greater than 90%.[3]

There remains an imbalance between demand and donor supply which has led to the development of innovative techniques to increase the pool of available donor organs. The increased availability of organ perfusion methods, such as abdominal normothermic regional perfusion, to reduce both warm and cold ischaemic injury and increase the utility of marginal donation after circulatory death (DCD) organs. Living donor transplantation and split-liver transplantation (LT) have further increased the availability of livers for recipients.

Despite these efforts, patients continue to wait extended periods for a donor organ. Such waits increase the risk of peri-operative complications and the development of critical illness before transplantation which can impair long-term outcomes.[4] In recent years the efficacy of LT for patients with acute-on-chronic liver failure (ACLF) has been proven and these patients now have increased access to organs, with acceptable post-LT outcomes of up to 94% survival at one year. [5]

Patient Selection for Elective Liver Transplantation

Successful listing of patients for LT can occur after they have met the selection criteria and been shown not to have any absolute contraindications or significant co-morbidity which would be associated with poor post-LT outcomes. The transplant assessment process has four main aims:

- To assess the severity of liver disease and confirm indications for LT.
- To assess for any physical co-morbidity which might impact post-transplant outcomes.
- To assess for any psychological or social factors which might impact post-transplant outcomes, including an assessment for both alcohol and substance use disorders.
- To recommend actions which will keep a patient in optimal physical and mental health whilst waiting for a donor organ to become available.

Selection criteria are broadly consistent across different global and regional organ allocation systems. The UK uses a minimal listing scoring system called the UK end-stage liver disease (UKELD) score, whilst internationally the model for end-stage liver disease (MELD) score is more commonly applied.

Contraindications to listing for liver transplant would generally be an expected poor post-transplant outcome (<50% survival at 5 years); active extra-hepatic malignancy, uncontrolled HIV infection or uncontrolled extra-hepatic sepsis.

End-stage chronic liver disease: The UKELD and MELD scores identify those patients with chronic liver disease in whom 1-year mortality without LT exceeds the expected post-LT mortality, and in most systems are the primary determinant of a need for listing. [6] In the United Kingdom, a

Transplant Benefit Score is used for the allocation of organs, identifying the recipient for a particular organ who is likely to obtain maximal transplant-free survival from transplantation.

Oncological indications: In addition to listing criteria based on hepatic function and symptomatic burden, a significant proportion of liver transplants are undertaken as curative treatment for hepatic malignancy (primarily hepatocellular carcinoma (HCC), which was the indication for 22.6% of liver transplants in the UK in the last 5 years.[3] Mazzafero et al. demonstrated a 4-year overall survival of 75% (with recurrence-free survival at 83%), which is close to that of patients with end-stage liver disease without malignancy.[7] More recent work by Duvoux et al. has shown that selection criteria for HCC can be expanded to include larger solitary tumours with favourable characteristics in response to locoregional therapy without a deleterious effect on recurrence and survival – those with a score of <2 after locoregional therapy have survival at 5 years approaching 70%.[8]

Recently LT has become a treatment option for neuroendocrine tumours, colorectal metastasis and hilar cholangiocarcinoma, the latter initially pioneered by the Mayo Clinic and including a protocol of neo-adjuvant radiotherapy and chemotherapy before transplant which demonstrated 5-year survival of between 64% and 71% compared with 18% with resection alone.[9]

Variant syndromes and non-elective indications: Some patients have a burden of liver disease, or a metabolic or genetic syndrome which can be cured by LT, but in whom the prognosis is not reflected by the organ severity scores. Such ‘variant syndromes’ include severe hepatopulmonary syndrome, polycystic liver disease, recurrent cholangitis, intractable pruritus and numerous inherited metabolic syndromes. Variant indications account for approximately 10% of all listings in the year 2022–2023. More recently there is growing evidence for the efficacy of LT in the setting of ACLF, with 94% survival at one year having been reported.[5]

Combined Organ Transplantation

Combined organ transplantation with LT includes simultaneous liver-kidney transplantation (SLK) and liver-lung or liver-heart transplantation. SLK is considered for patients with genetic liver and kidney syndromes (e.g. primary hyperoxaluria); patients with end-stage renal disease on long-term renal replacement therapy (RRT), or those with hepatorenal syndrome who have required RRT for more than 6 weeks. In addition, patients with end-stage liver disease who have an eGFR of <30 mL/min at the time of assessment should be considered. Regarding combined LT with a cardiothoracic organ, patients would usually have to meet listing criteria for both organ selection systems to be listed.

Peri-Operative Fitness for Transplantation

The physical assessment of a patient referred for liver transplant involves a thorough history of hepatic and extra-hepatic co-morbidity, physical examination, blood tests, imaging of the head, thorax, abdomen and pelvis and assessment of the cardiovascular system.

Peri-operative outcome scoring systems such as the P-SOFT (pre-allocation survival outcomes following LT), BAR (balance of risk) score and LTRS (liver transplant risk score) employ a number of recipient factors but all include recipient age and the requirement for any organ support before transplantation. [10-12] Older age is associated with a reduced 1 year survival, although there is no defined age ‘cut-off’. [13], [14]

Both P-SOFT and LTRS scores include body mass index (BMI) in their models. Obesity is increasingly common and metabolic-associated steatotic liver disease is a leading indication for transplantation. Post-operative infection, wound dehiscence and ventilator dependency are more prevalent, with cardiovascular complications the main cause of mortality. Those with diabetes or coronary artery disease in conjunction with obesity are 40% less likely to reach 5-year survival. [15] There are no BMI thresholds for listing; prior to surgery, medical co-morbidities as well as weight loss and dietary changes should be actively optimised. [16]

1. **Cardiovascular disease and metabolic risk factors**

Cardiovascular disease remains one of the main causes of death post-liver transplant – a recent cohort study identified cardiovascular disease as being significantly associated with increased mortality both in the immediate post-operative period and over the medium and long term. In particular, the presence of cardiac dysfunction is associated with higher early post-op mortality: within this, cirrhotic cardiomyopathy presents a specific concern and risk for post-operative cardiac failure.[17,18]

Cardiovascular fitness and reserve is a key consideration, given the physiological stress of transplantation. This includes cross-clamping of the major vessels, the prospect of large intra-operative blood loss, the haemodynamic effects of large fluid shifts, as well as the physiological insult of hepatic reperfusion. As such, patients should at least demonstrate adequate ventricular systolic and diastolic function: diastolic dysfunction can indicate cirrhotic cardiomyopathy, which can also lead to a prolonged QT interval increasing the risk of arrhythmias in the intra-operative and post-operative periods.[19]

In addition to a baseline ECG and echocardiogram, a broader assessment of cardiovascular risk should consider risk factors for coronary artery disease. This is pertinent as undiagnosed inducible myocardial ischaemia may result in life-threatening complications in the peri-operative period. Moreover, there is a risk of acceleration of pre-existing cardiovascular disease after transplantation on account of the long-term effects of immunosuppression, including hypertension and diabetes.

Such an assessment should include blood pressure, BMI, ascertaining family history of coronary artery disease and a smoking history. For these patients, additional investigations should be considered, including cardiac stress testing, CT or invasive coronary angiography. Cardiopulmonary exercise testing has been shown to predict cardiorespiratory reserve, and a low anaerobic threshold is associated with increased post-operative complications. [20]

In those patients with concurrent risk factors for vascular disease, carotid and lower limb Doppler studies can be considered in order to assess the risk of other macrovascular complications (stroke or critical limb ischaemia) in the peri-operative period. Diabetes is present in 23.9% of patients on the waiting list, and its prevalence is increasing. [21]

2. **Renal dysfunction**

   Renal dysfunction in patients with cirrhosis is associated with reduced post-transplant survival, both in patients with acute kidney injury and in those with chronic kidney disease. [22]

   Of note, post-liver transplant outcomes in patients with chronic kidney disease are significantly worse than those without renal dysfunction prior to transplantation, making the case for combined transplantation where feasible. [23] Hepatorenal syndrome increases the complication rate and reduces survival following transplantation, with renal function not recovering by up to 25%. Assessment should be focused on trying to identify chronic and irreversible renal disease using urinalysis and renal imaging.

3. **Respiratory disease:**
   a. **Hepatopulmonary syndrome**

      Hepatopulmonry syndrome (HPS) is thought to be the result of intra-pulmonary vascular dilatation and subsequent intra-pulmonary right to left shunting of deoxygenated blood, resulting in hypoxaemia. [24] HPS is present in between 5%

and 30% of liver transplant recipients. The most sensitive indicator for the presence of HPS is hypoxaemia at rest – oxygen saturations of less than 96% on room air without an alternative explanation, are highly sensitive for detecting HPS and should warrant an arterial blood gas in order to ascertain the degree of hypoxaemia. HPS is confirmed with either a contrast-enhanced transthoracic echo with agitated saline (‘bubble’ echocardiogram) or with a technetium-99 labelled macro-aggregated albumin scan.

HPS is a variant indication for transplantation on account of its association with reduced survival when compared with patients with the same degree of chronic liver disease but without HPS: 5-year survival for matched cases with and without HPS were 23% and 63% respectively in one study. [25]

Despite an increase in mortality in the first year post-transplant, long-term outcomes are comparable to those transplanted without HPS. Post-transplant mortality is increased especially if hypoxaemia is severe (paO2 <6.0 kPa). This is predominantly restricted to the early post-transplant period. [26] The degree of hypoxaemia prior to transplant correlates with the length of time required post-transplant before this resolves, and may impact on short-term survival.

Refractory hypoxaemia can be treated with Trendelenberg positioning, intravenous methylene blue, inhaled nitrous oxide or veno-venous extracorporeal membrane oxygenation (VV-ECMO) if the shunt is severe. [27]

Post-operatively, patients with significant HPS may require prolonged periods of respiratory support and high-flow nasal oxygen delivery can be particularly helpful. Gradual weaning of oxygen after transplantation is key in order to reduce the risk of organ hypoperfusion whilst the shunt resolves.[28]

b. **Portopulmonary hypertension**

Portopulmonary hypertension (PoPH), an elevated mean pulmonary arterial pressure (mPAP, >20 mm Hg) with increased pulmonary vascular resistance (PVR, >160 dynes/s/cm^{5}) and low pulmonary capillary wedge pressure (PCWP, <15 mm Hg) ruling out volume overload, is seen in around 6% of patients with chronic liver disease.[29] PoPH is associated with worse outcomes at 1 (85%) and 3 years (38%–68%) after transplantation and is not necessarily directly associated with the severity of liver disease.[30] Patient with an estimated pulmonary artery systolic pressure >45–50 mm Hg on echocardiogram should undergo further diagnostic testing, for example with right heart catheterisation.

A combination of shear stress, endotoxaemia and shunting of mediators via porto-systemic collaterals have been suggested as potential triggers for pulmonary vascular endothelial injury, remodelling and arterial smooth muscle proliferation. PoPH can, in itself, be an indication for transplantation, however, not all cases are treated definitively by transplantation: in some cases, pulmonary pressures can remain static or worsen. Therefore the selection of those patients who would benefit from transplantation is key.

If patients have a mPAP <35 mm Hg they can proceed to LT listing with appropriate monitoring on the wait list. If the mPAP is >35 mm Hg patients should be commenced on oral pharmacotherapy in order to reduce the mPAP to <35 mm Hg and the pulmonary vascular resistance (PVR) to <240 dynes/s/m^{5} . If this cannot be achieved and the mPAP remains elevated then LT is contraindicated.[31]

c. **General respiratory disease**

Pleural effusions, atelectasis, lobar collapse and pneumonia are common complications in the immediate post-operative period and patients must have sufficient respiratory reserve to overcome such a complication without prolonged hypoxaemia, which could compromise liver graft function.[32] Obstructive airways disease is predominantly related to smoking but also to alpha-1-antitrypsin deficiency, which accounts for approximately 1% of LT. The severity of chronic respiratory disease may be a contraindication for transplantation if it is felt that this would increase the risk of pulmonary complications in the post-operative period. Smoking cessation is often a pre-requisite for transplant listing. In a similar vein, the presence of interstitial lung disease should be evaluated and if idiopathic pulmonary fibrosis is diagnosed, this is usually a contraindication to transplantation on account of its progressive nature and limited 5-year survival.

Hepatic hydrothorax is present in 10%–15% of patients with cirrhosis and ascites and refractory hydrothorax has a high short-term mortality.[33] Bridging to LT may require a TIPS for short-term control of the effusion, or repeated thoracocentesis in those patients in whom TIPS is contraindicated.

4. **Sarcopenia**

   Sarcopenia is associated with poorer outcomes after LT – this may reflect an impaired physiological reserve, reflected in longer recovery times, longer length of stay in intensive care, ventilator dependency, increased rates of infection. Muscle mass also reflects the degree of advanced liver disease at the time of transplantation, a factor long known to be associated with poorer outcomes. [34] Sarcopenia is measured using mid-arm muscle circumference or measurement of psoas muscle at the level of L3. Scoring systems have been validated to measure the risk of mortality whilst waiting for transplant (Liver Frailty Index) and in the post-transplant period (Karnofsky Performance Status and Braden Scale). [35] Notably, sarcopenia is observed in obese patients with metabolic liver disease and should be universally screened for. [36] Optimisation pre-operatively should include optimal nutrition, using enteral feeding if necessary, and a programme of prehabilitation. [37]

The Listing Process: Referral, Assessment, Listing Meeting and Outcomes

The process of accepting a patient onto the national waiting list for a liver requires the patient to meet criteria set out by national transplant services. Urgent listing is a separate process and is covered in Chapter 54 ; it is based on the presence of poor prognostic factors in patients with acute liver failure or acute-on-chronic liver failure.

Referral for assessment for elective LT involves formal referral to a local transplant centre, outlining the indications for transplantation, markers of disease severity and history of medical therapies or other interventions (i.e.

paracentesis, diuretics, TIPSS insertion and immunosuppression). In addition, a clear history of relevant co-morbidities (metabolic risk factors and history of prior non-hepatic malignancy in particular) is pertinent, in addition to a clear history of alcohol, smoking and any issues with dependency on illicit drugs.

Referrals are then reviewed in a dedicated assessment service, and a multi-disciplinary review is assisted by specialist input from anaesthetists, surgeons, dieticians and physiotherapists, as well as from dedicated specialists in substance misuse and psychology. These opinions are synthesised within a transplant multi-disciplinary team meeting and if it is agreed that the patient meets selection criteria for transplantation, they are activated on the national transplant wait list thereafter.

Waiting List Management

Once a patient has been registered on the elective waiting list, they must be regularly monitored to ensure that they remain eligible. This is particularly pertinent for those patients with an oncological indication for transplantation, whose cancer may progress beyond criteria, or people who have received treatment for underlying liver disease who may improve to the point that transplant is no longer required. People on the waiting list receive regular blood tests, and imaging and repeat cardiovascular testing for those who have prolonged waiting or for those with increased risk.

In the UK 10% of patients died within a year of being listed for elective liver transplant, rising to 12% at two years. [3] The wait for an organ varies with centre and blood type; the median wait is 119 days in the UK, but this can range from 50 to 221 days. Therefore physiological optimisation in advance of transplantation should remain a priority, including: optimal nutrition, ongoing abstinence from alcohol, control of the aetiological factor(s) and cessation of smoking. Patients may be offered transjugular intrahepatic porto-systemic shunt (TIPS) insertion whilst awaiting transplantation if recurrent ascites or variceal bleeding are particular concern.

Management of symptoms of end-stage liver disease should be a focus; some patients may require input from palliative care; furthermore, deterioration with worsening frailty may trigger re-evaluation of the feasibility of transplant and prompt re-discussion in the transplant multidisciplinary meeting. Episodes of acute deterioration or sepsis may result in suspension from the waiting list. The waiting list clinic offers an opportunity to continually evaluate the patient’s wishes and expectations as well as to educate them about the process and answer questions.

Operative Procedure

LT involves three key phases – firstly, the recipient hepatectomy with ligation of major vessels (including the recipient portal vein, hepatic artery and hepatic inferior vena cava) and bile ducts. This can be the most high-risk phase for blood loss and the most time-consuming, particularly if there is a large burden of varices and porto-systemic shunts. Prior bacterial peritonitis, hepatic ablations or resections can increase the prevalence of adhesions.

The next, ‘anhepatic’ phase commences with clamping of the recipient’s hepatic inferior vena cava (and subsequent removal of the recipient’s native liver) and continues until the donor vessels are anastomosed and the organ perfused. Fluid shifts and visceral ischaemia during this period are particularly common; these are reduced through the use of the piggyback caval anastomosis method of implantation, which allows for partial clamping of the recipient’s inferior vena cava. Donor hepatic inferior vena cava or hepatic veins are grafted directly onto the recipient inferior vena cava (IVC), either in a side-to-side or end-to-side fashion. Thereafter the portal vein is anastomosed. Portal venous thrombosis is no longer a contraindication to transplantation – but patients may require thrombectomy or venous grafts. Such conduits and grafts are normally fashioned from donor vessels; if reconstruction is required this is usually planned in advance and arterial anastomosis and reperfusion may be prioritised in order to reduce the impact of warm ischaemia.

The third key phase, reperfusion, involves allowing portal inflow to reperfuse the liver and systemic circulation. This is another key point at which complications can occur, as blood rich in potassium and other products of prolonged cold and warm ischaemia from the viscera and donor’s liver enter the systemic circulation. The ‘post-reperfusion syndrome’ describes a combination of hypotension and vasodilatation, bradycardia and arrhythmia, pulmonary hypertension and hyperkalaemia. In some cases, cardiac arrest can occur. The aetiology is unclear, but a sudden increase in venous return, release of vasoactive substances, and cold potassium-rich preservation fluids are potentially implicated. The donor organ is usually flushed with blood or albumin directly after it is anastomosed, but before the portal venous inflow is allowed to fully reperfuse the liver, to attempt to attenuate this effect.

Reperfusion syndrome usually resolves within 5 minutes, with appropriate fluid loading and correction of electrolytes. In approximately 30% of patients, it lasts for significantly longer and can require vasopressor and inotropic support. Post-reperfusion syndrome is more common in organs with longer preservation times and may be associated with early allograft dysfunction related to ischaemia-reperfusion injury suffered by the graft.

Thereafter, the arterial and biliary anastomoses are completed. Biliary anastomoses are generally performed end-to-end between the donor and recipient and subsequent recipient cholecystectomy. In some centres, in patients with primary sclerosing cholangitis or for anatomical reasons the recipient bile duct is not retained and a hepaticojejunostomy is formed; this is in an effort to reduce the risk of further stricturing and/or malignant transformation in the native recipient duct. [38]

Intra-operative ultrasound is now often used to assess the vascular patency and waveform of venous and arterial blood flow before completion of the procedure.

Intra-Operative Monitoring

There remains no consensus on the tools used for intra-operative monitoring and a combination of trans-oesophageal echo, central and/or peripheral arterial monitoring and pulmonary artery catheters are used depending on local preferences and expertise. Central venous access is required for vasopressors and electrolyte replacement and large-bore access such as multi-lumen access catheters required for rapid volume resuscitation. The anticipated large shifts in venous return during the anhepatic phase and reperfusion make a persuasive argument for prompt and expedient filling of the peripheral vascular compartment; however, this can have significant deleterious consequences after reperfusion with volume overload, interstitial oedema and it can make intra-operative bleeding and coagulopathy more pronounced. [39]

Intra-Operative Coagulopathy and Blood Loss

LT can be associated with massive blood loss due to a host of factors. These include coagulopathy secondary to end-stage liver disease, portal hypertension and surgical complications including vascular injury and those related to adhesions. Haemostasis can alter intra-operatively and should be monitored dynamically. Coagulation in end-stage liver disease is a balance of anti-haemostatic and pro-haemostatic drivers and these are exacerbated by surgery, especially during the anhepatic phase when both fibrinolysis and platelet dysfunction can accelerate. Metabolic acidosis can lower fibrinogen levels and increase transfusion requirements. Overzealous transfusion carries significant risks to both electrolyte imbalances, hypothermia and hypervolaemia intra-operatively and should therefore be guided by the use of thromboelastography (TEG) or rotational thromboelastometry (ROTEM). In addition, use of cell salvage techniques is now commonplace to allow for autologous transfusion of red cells and reduce the risk of transfusion-related harms such as acute (immune-mediated) lung injury (TRALI). Fibrinogen and prothrombin complex concentrates can help to stabilise clot formation in the anhepatic and early post-hepatic phase without the excessive volume requirements of fresh frozen plasma or cryoprecipitate. Indeed, some patients within this population are pro-thrombotic (those with pre-existing mesenteric thrombosis or Budd-Chiari, for example) and may require expedient anti-coagulation post-operatively. Similarly, patients with high-risk or complex arterial or venous anastomoses may be given heparin intra-operatively to prevent early thrombosis and graft loss. [40]

Immediate Recovery and Post-Liver Transplant Complications

The immediate post-operative monitoring should take place in the critical care unit, where patients can be monitored for any LT-related complications. The most commonly encountered complications are listed in Table 116.1 . A frequent challenge can be the discrimination between early bleeding and allograft dysfunction, which can both present with increasing vasopressor requirements and hyperlactataemia.

Table 116.1

Most commonly encountered post-liver transplant complications

EARLY COMPLICATIONS

Haemorrhage
Hepatic artery thrombus
Early allograft dysfunction
Primary non-function
Infections (bile leak, respiratory, surgical site, CMV infection)
Acute cellular rejection
Biliary strictures
Acute kidney injury
Delirium/cognitive impairment
Portal vein thrombosis

LATE COMPLICATIONS

Biliary strictures
Recurrence of primary liver disease
Bacterial/fungal infections
Chronic kidney disease
Acute or chronic rejection
New-onset diabetes after transplantation
Cardiovascular disease
Late vascular thrombosis (hepatic artery or portal vein)
Malignancy, including post-transplant lymphoproliferative disease

Enhanced recovery programmes for post-LT patients have been established and patients can be proactively extubated before transfer to the post-operative intensive care. Early feeding, removal of vascular catheters and drains can promote mobilisation and reduce the risk of nosocomial infection as well as reducing both ICU and hospital LOS. [41]

The type of liver graft used can have specific relevance intra-operatively and in the immediate post-operative period. Donor after brain death (DBD) organs are the most common type of graft utilised in LT. There is an increasing utilisation of DCD livers – 36% of all liver transplants in adults in the UK in the year 2022–2023 were with this type of graft.

LT with DCD livers is more commonly complicated by reperfusion syndrome, particularly in those with prolonged donor warm ischaemic times. Thereafter, concerns remain about the higher incidence of early allograft dysfunction – incidences range between 30% and 44%, compared with 15% and 30% in patients who received a liver donated after brainstem death. [42] In addition, a higher rate of ischaemic cholangiopathy has been a key area of concern – this diffuse process can result in re-transplantation if the cholangiopathy is extensive and diffuse. It has been reported in meta-analyses to be over ten times more likely to occur after DCD transplantation, with rates of 16% compared to 3% after DBD transplantation, with the majority of cases occurring within the first 120 days. Of note, rates of ischaemic cholangiopathy have been reported to be significantly lower (less than 10%) with newer graft perfusion techniques such as normothermic regional perfusion. [43]

Cardiovascular: Haemodynamic changes after LT are common; hypertension with an increased systemic vascular resistance is frequent and may be due to the restoration of normal liver function and portal pressure, as well as the hypertensive effect of the calcineurin immunosuppressants. The increased afterload in the early post-transplant period may unmask cardiac dysfunction. Management of myocardial failure post-LT is largely empirical; diuretics, afterload reduction and positive-pressure ventilation may all be required.

Neurological : The quoted incidence of central nervous system (CNS) complications varies widely from 10% to 40%. Most neurological complications occur within the first month of the transplant. Non-alcohol-related fatty liver disease, a previous history of neurological disease, recipient age (specifically age above 50 years old), a previous history of hepatic encephalopathy and admissions related to hepatic encephalopathy, the use of DCD grafts, the use of post-LT renal sparing immunosuppression and the presence of post-LT sepsis are associated with post-LT delirium. [44] The calcineurin inhibitors (CNIs) are associated with tremor, seizures and altered conscious level.

Renal: AKI is a relatively common complication, with an incidence of between 25% and 60% and a multifactorial aetiology. Risk factors include the presence of pre-transplant co-morbidity (e.g. hypertension, diabetes mellitus, obesity and HRS), severity of underlying liver disease, intra-operative instability, blood product requirement, hepatic ischaemic reperfusion injury, drug toxicity, graft dysfunction and higher risk grafts. [45] Intra-abdominal hypertension should always be considered in the post-transplant setting as a potential contributor not only to renal dysfunction but also to cardiorespiratory embarrassment. Early consideration should be given to laparostomy in patients with elevated intra-abdominal pressures and associated organ dysfunction. [46]

Acute Allograft Rejection

Acute cellular rejection becomes a risk from approximately 5–7 days post-transplant; the clinical signs of rejection are non-specific and include fever, deterioration in graft function and a rapid rise in serum aminotransferase concentration. Liver biopsy is the only reliable diagnostic tool; however, biopsy may be relatively contraindicated due to coagulopathy. In some circumstances, transjugular biopsy offers a solution to this problem. The normal management regime for an episode of acute rejection is that of pulsed methylprednisolone (500-1000 mg daily for 3 days), though approximately 10% will develop steroid-resistant rejection. Anti-thymocyte globulin, a polyclonal lymphocyte antibody preparation, is often used in liver transplant centres to treat steroid-resistant rejection.

Bacterial and Fungal Infections

LT recipients are uniquely vulnerable to infection with up to 80% developing at least one infection during the first year. [47] RRT Commonly encountered pathogens are Gram-positive bacteria (enterococci and staphylococci), Gram-negative enterobacteria and a concerning emergence of multiple antibiotic-resistant bacteria, in particular vancomycin-resistant enterococci and multidrug-resistant Gram-negative organisms. Opportunistic fungal infections remain problematic. Candidiasis is the most frequent fungal infection and the leading cause of invasive fungal infection. Risk factors for invasive candidiasis include: previous use of prophylactic antibiotics for spontaneous bacterial peritonitis, RRT, re-transplantation, technically difficult surgery, intra-operative blood transfusion and prolonged ICU stay. [48] *Aspergillius* spp. are the second most common fungal infection, though diagnosis can be difficult, and often involves invasive procedures. Non-invasive serological markers, including 13-b-glucan (BDG) and aspergillus galactomannan, can be used as diagnostic indicators. The use of prophylactic antifungals is now widespread in those with risk factors, but consideration of drug-drug interactions, particularly those with CNIs, is important. [49]

Cytomegalovirus (CMV) Infection

CMV Infection is rarely associated with symptomatic illness in healthy hosts but is a major cause of morbidity and mortality in LT recipients; it is the single most common opportunistic infection after solid organ transplantation. In the absence of anti-CMV strategies the overall incidence of CMV infection after LT ranges from 23% to 85%, with approximately 50% of those developing clinical disease. CMV infection most commonly occurs in the first 3 months after LT, with a peak incidence in the third and fourth week. Infection may be asymptomatic, or it may cause a spectrum of illness including fever, thrombocytopenia, neutropenia, pneumonia and hepatitis. The indirect effects of infection probably contribute more to the adverse effects on graft function than direct effects. The risk of CMV infection post-transplant is dependent on the serological status of both the donor and recipient; the highest risk is associated with donor positive/recipient negative. [50] UK guidelines suggest prophylaxis in high-risk groups with anti-CMV therapy, such as valganciclovir. [51] CMV-specific immunoglobulin is frequently added in the management of CMV pneumonitis. [52]

Immunosuppression

Most LT recipients require lifelong immunosuppression, and a balance must be struck between the optimal prevention of rejection and the toxicity and unwanted effects of the drugs. Induction regimens using IL-2 receptor blockers are usually employed in order to reduce early calcineurin inhibitor (CNI) dose for patients at risk of acute kidney injury (AKI). CNI's are the backbone of immunosuppression strategies and monotherapy, usually with tacrolimus, is possible in many patients. [53] Mycophenolate mofetil or Azathioprine are added when enhanced regimens are required, such as after an episode of rejection, or for patients with auto-immune disease. Future strategies for limiting the long-term sequelae of immunosuppression hope to utilise the unique hepatic immunological environment and induce tolerance so that immunosuppression could be withdrawn.

Paediatric Liver Transplantation

LT is the treatment of choice for children with end-stage liver disease. Cholestatic disorders make up the largest indication for transplantation, with extra-hepatic biliary atresia plus or minus previous Kasai porto-enterostomy accounting for over 50% of paediatric transplants. Metabolic diseases and primary hepatic tumours are also common indications. As in adult recipients, multisystem effects of end-stage liver disease are common, and the occurrence of liver disease as part of a congenital syndrome (e.g. Alagille's) may warrant invasive pre-operative evaluation of extra-hepatic manifestation. Scarce availability of paediatric donors has driven innovations such as reduced-size grafts, split-liver techniques and living donor programmes, which have all contributed to expand the pool of available donors and reduced the mortality for those children waiting for suitable organs. Associated cardiac, pulmonary or renal abnormalities observed in some paediatric syndromes with liver disease may require particular attention and management such as the pulmonary stenosis seen in association with Alagille syndrome. Five-year survival rates of 94% have brought about a new set of challenges relating to complications and management of long-term immunosuppression through adolescence and into early adulthood.

Kidney Transplantation

Introduction

Kidney transplantation (KT) is the preferred form of RRT for the majority of adults with end-stage kidney disease (ESKD), providing a better quality of life and a longer life when compared to long-term dialysis. However, KT requires sufficient cardiorespiratory reserve to tolerate major abdominal surgery, and a patient who is willing and able to adhere to prolonged immunosuppression. Therefore not all patients with ESKD are deemed suitable for KT.

For those adults who do receive a KT, outcomes are generally very good. Patient survivals at 5- and 10-years post-transplant are 85%–95% and 65%–85%, respectively, with death-censored graft survivals of approximately 85%–95% and 70%–85% at five- and 10-years post-transplant, respectively.[54]

On occasion, KT can be performed along with another form of organ transplantation such as pancreas transplantation (PT) (simultaneous pancreas-kidney transplantation), or simultaneous heart-kidney or liver-kidney transplantation. This chapter focuses on kidney-only transplantation, with a section on PT later.

Candidate Selection and Work-Up

KT can be performed on patients already on other forms of RRT such as haemodialysis or peritoneal dialysis, or before dialysis is needed (pre-emptive transplantation). Pre-emptive transplantation is preferred, as it avoids the morbidities and costs of dialysis. However, due to waiting times for KT from a deceased donor, pre-emptive transplantation most commonly occurs with a kidney transplant from a living donor.

All forms of transplantation require potential transplant recipients to be sick enough to warrant the dual risks of surgery and long-term immunosuppression, and fit enough to withstand these insults and their associated complications. Furthermore, there needs to be adequate space within the pelvic or abdominal cavities for a kidney transplant, and appropriate arterial inflow and venous outflow vessels. Urinary outflow also needs to be considered (see ‘Operative technique’ later). KT is not considered in those with acute kidney injury, as temporary forms of RRT are more appropriate.

Indications, absolute contraindications and relative contraindications are shown in Table 116.2 . There are no formal recipient upper or lower age or BMI thresholds for KT in the UK, with an age range between 2 and 80 years, though elderly patients tend to have more age-related co-morbidities that may render KT unacceptably risky.

Table 116.2

Indications, absolute contraindications and relative contraindications of KT

INDICATIONS

End-stage kidney disease (estimated glomerular filtration rate <15 mL/min/1.73 m^2)

ABSOLUTE CONTRAINDICATIONS

Uncontrolled cancer
Active systemic infections
Any condition with life expectancy <2 years

RELATIVE CONTRAINDICATIONS

Predicted survival of <5 years (excluding patients with imminent loss of dialysis access)
Predicted risk of kidney graft loss of >50% at one year
Likely inability to adhere to immunosuppression regimens
Immunosuppression likely to cause life-threatening complications

---

Adapted from UK national policies (https://www.odt.nhs.uk/transplantation/tools-policies-and-guidance/policies-and-guidance/).

Before KT can occur, assessments and tests are needed to assess candidate suitability and to enable donor-recipient matching (Table 116.3). Cardiovascular risk factors in potential kidney transplant recipients include[55]:

- diabetes mellitus
- prior cardiovascular disease
- >1 year on dialysis
- left ventricular hypertrophy
- age >60 years
- smoking
- hypertension
- dyslipidaemia

Table 116.3

Work-up assessments and tests required prior to KT

DONOR-RECIPIENT MATCHING
Blood group
Human leukocyte antigen (HLA) typing and anti-HLA antibody screening
TECHNICAL FEASIBILITY
Clinical assessment (history-taking, clinical examination including groin and foot pulses)
Imaging of iliac arteries and veins (e.g. with ultrasonography)
Bladder functional assessment (in those with known or suspected bladder dysfunction)
OTHER CONSIDERATIONS
Microbiological screening (e.g. hepatitis B and C, HIV, HTLV, syphilis, CMV, EBV and VZV)
Cardiorespiratory fitness (e.g. ECG, echocardiogram, cardiac stress tests and lung function tests, CXR)
Psychological evaluation (e.g. in those with previous adherence issues, or drug and alcohol abuse)
Recurrence of renal disease
Cancer screening tests according to national cancer screening programmes

Adapted from UK national policies (https://www.odt.nhs.uk/transplantation/tools-policies-and-guidance/policies-and-guidance/).

The presence of three or more risk factors should prompt pre-transplant evaluation of cardiovascular disease. [56] However, the evidence base for some screening tests (e.g. cardiac stress testing in asymptomatic patients with ESKD) is not strong, and therefore work-up policies will vary between units. Final decisions on suitability for KT should be made by a multidisciplinary team including a consultant nephrologist and a consultant transplant surgeon.

Donor Options

KT can be performed either from a living donor or a deceased donor (donation after brain death (DBD) donor or donation after circulatory death (DCD) donor). Living donor KT is considered to be the ‘gold standard’ RRT option as it can be performed as a planned procedure, with far lower rates of delayed graft function and slightly superior long-term graft survivals when compared to deceased donor KT. Living donor KT also avoids the prolonged wait for a deceased donor organ and the risks of progressive co-morbidities (and subsequent mortality) associated with accrued time on dialysis. Deceased donor KT often carries with it additional uncertainties about donor-related risks due to the time pressures inherent in the deceased donation pathway.

In the UK, of the approximately 3000 kidney transplants that are performed per year, about one-third are from living donors. The living donor can be related or unrelated (e.g. partner or friend). The potential live kidney donor candidate requires extensive assessment to ensure that they are fit enough to donate a kidney and have sufficient remaining kidney function for the remainder of their life. A live donor nephrectomy is most commonly performed laparoscopically (hand-assisted or total laparoscopic technique), though robotic-assisted nephrectomy may also be an option in some units. The risk of early post-donation mortality is approximately 1 in 10,000.

For those donor-recipient pairs that are blood group- or human leukocyte antigen (HLA)-incompatible (or both), there are two further options. If the recipient’s antibody titres directed against the donor are relatively low, direct antibody-incompatible KT can still occur, though with the need for augmented immunosuppression (sometimes with pre-transplant plasma exchange) and with an increased risk of early graft rejection and graft loss. Alternatively, multiple incompatible pairs can enter into national or regional living donor kidney-sharing schemes, where matching algorithms can identify compatible pairs. For instance, Donor (D) 1 and Recipient (R)1 may be incompatible, as are D2 and R2, but R2 may be able to receive an antibody-compatible organ from D1, and R1 from D2 (Table 116.4). This can lead to two-way or three-way exchanges, or more complex sharing arrangements.

Table 116.4

For those patients who do not have a living donor, activation in the national waiting list for a deceased donor kidney can be considered. Waiting times for deceased donor KT vary widely between countries, but in the UK the median wait is approximately 2–2.5 years. Many other factors influence waiting time including:

- degree of HLA sensitisation
- blood group
- recipient age
- willingness of the transplant unit to accept organs perceived as higher risk

KT from DCD donors is increasingly common in many countries; although delayed graft function rates are higher after KT from DCD versus DBD donors, it appears that longer-term outcomes are broadly equivalent.[57] Furthermore, cold ischaemic time tolerances are shorter in DCD organs, with reductions in graft survival seen when cold ischaemic times are >12 hours, as opposed to >24 hours in DBD donor KT.[58], [59]

Operative Technique

After the induction of general anaesthesia, placement of lines and a urethral catheter, and administration of immunosuppression and prophylactic antibiotics, the standard technique for KT is via a 15–20 cm long incision in either the right or left groin with a space developed in the extraperitoneal plane down to the external iliac artery and vein. These two vessels are mobilised, with clamping of the vein and an end-to-side anastomosis with the graft renal vein, followed by clamping of the artery and an end-to-side anastomosis with the graft renal artery. On removal of the vascular clamps, recipient blood perfuses the organ, and haemostasis is secured with additional sutures as needed. If graft perfusion looks acceptable, with a pink well-perfused organ, the anastomosis between the transplant ureter and the recipient's bladder can be completed. Most units routinely place a transplant ureteric stent within this anastomosis in order to reduce the risk of urine leaks or transplant ureteric stenoses (see below). [60] Many surgeons place a drain in the deep extraperitoneal (peri-nephric) space before closing the muscles and skin. Average operating times are 2.5–4 hours, with typical blood losses of 50–300 mL.

There are many variants of the previous approach depending on surgeon preference, and the anatomy of the organ and recipient. The kidney can be placed in the intraperitoneal space, or alternative target vessels such as the inferior vena cava/aorta or common iliac vein/artery can be utilised.

In recipients with complex bladder pathologies, many different approaches for establishing urine outflow can be considered, including a transplant ureteric anastomosis to the recipient's skin (cutaneous transplant ureterostomy), anastomosis of the transplant ureter to a pre-existing ileal conduit or anastomosis to a previously augmented bladder with drainage via a Mitrofanoff conduit.

Intra-Operative Monitoring

The degree of intra-operative monitoring required will vary according to the patient and the likely complexity of the transplant. Most transplant units will require a central venous line, peripheral cannulae and a urethral catheter at a minimum. Older recipients, those with cardiovascular co-morbidities, and patients undergoing re-do or complex surgery require arterial line placement. The use of intra-operative cardiac output monitoring devices varies widely but is increasingly common. Delayed graft function (DGF) is common in deceased donor KT, and recipients of organs where DGF is likely should have a functioning dialysis access in place post-transplant.

Fluid Replacement

Adult patient transplant recipients receive 2000–3000 mL of fluids intra-operatively to fill the intravascular compartment, avoid hypotension and reduce the risk of subsequent DGF and graft thrombosis. A recent randomised controlled trial has suggested that a balanced low chloride crystalloid solution (Plasma-Lyte 148) is superior to normal saline in the avoidance of DGF when used intra-operatively and for the first 48 hours after post-transplant.[61] Transfusion triggers are generally 70–75 g/L of haemoglobin in an attempt to avoid the potassium load within packed red blood cells and HLA sensitisation to passenger leucocytes.

Post-Operative Care

The majority of transplant recipients have an uncomplicated post-operative course that does not require ICU admission. Early ICU admission rates after kidney transplant surgery have been reported at 15%–20% and admission criteria include[62]:

- systolic blood pressure less than 90 mm Hg in two consecutive measurements that does not respond to fluid resuscitation
- post-transplant reduction in systolic blood pressure greater than 20% compared with the pre-transplant measurement
- new-onset cardiac dysrhythmia associated with haemodynamic instability

KT is associated with a reduction in overall long-term mortality, but with increased short-term post-transplant cardiovascular mortality.[63,64] In one study, cardiovascular events within three months after transplantation were reported in 8.6% of recipients.[65]

Additional practical factors leading to ICU admission may include:

- need for renal replacement therapy in the ICU, specifically out-of-hours when acute haemodialysis services may be unavailable on the ward
- high BMI >30 kg/m^2 with or without obstructive sleep apnoea needing continuous positive airway pressure therapy

- high-risk transplants with previous early graft failure where closer monitoring is required
- small stature patients who have had paediatric renal disease affecting growth affecting fluid balance and medication management

Immunosuppressive Strategies

Kidney transplant recipients require immunosuppression for the life of the graft. Immunosuppression can be classified according to mechanism of action (monoclonal antibody, polyclonal antibodies, calcineurin inhibitors, steroids, etc.), or timing of administration (induction versus maintenance). Preferred immunosuppressive approaches vary between countries and units. Many UK transplant units use high-dose intravenous steroids and a monoclonal antibody at induction (e.g. basiliximab, an IL-2 receptor blocker), followed by maintenance immunosuppression with tacrolimus, mycophenolate mofetil and a tapering dose of oral prednisolone.

These immunosuppressants have a broad array of complications including an increased risk of infection (see below), impaired wound healing, an increased risk of malignancy (especially non-melanoma skin cancers and lymphoma), diabetes mellitus, diarrhoea, myelosuppression, hypertension and hypercholesterolaemia.

Early Post-Transplant Issues and Complications

Delayed graft function : There are many definitions of delayed graft function (DGF), but the most widely used is ‘any form of dialysis in the first 7 days post-transplant’. [66] In essence, DGF implies that the function of the transplanted organ is insufficient to meet the biochemical demands of the recipient. It also implies that graft function will eventually recover (‘delayed’ rather than ‘permanent’), though this cannot be known definitively at the time. Rates of DGF are influenced by donor type (DCD 40%–60%, DBD 20%–40%, living donor 2%–5%), prolonged cold ischaemic time, recipient hypotension and many other factors.

The most common cause of DGF is ischaemia-reperfusion injury of the transplanted kidney, which usually settles within two weeks post-transplant. Other causes of DGF include allograft rejection and urinary outflow obstruction. Recipients with DGF should undergo an ultrasound of the transplant to exclude urinary obstruction (and confirm perfusion of the graft) and may need a graft biopsy to identify graft rejection if DGF persists beyond 5–10 days post-transplant.

Primary non-function (PNF): Failure of the transplanted kidney to ever render the recipient free from dialysis is known as PNF. This is most commonly due to severe early allograft rejection or graft thrombosis (arterial or venous). Rarely, PNF may also be caused by aggressive early recurrent renal disease (e.g. atypical haemolytic uraemic syndrome or primary focal segmental glomerulosclerosis) or prolonged ischaemic times. PNF occurs in approximately 2-5% of recipients. Diagnosis is usually obtained after graft imaging (ultrasonography ± computed tomography) and graft biopsy. On occasion, it can be difficult to distinguish between prolonged DGF and PNF, though the failure of a graft to function at three months post-transplant usually suggests that the transplant will never eventually function.

Vascular complications : KT is fundamentally a vascular procedure, and the most devastating complications post-transplant are often vascular in nature. Bleeding from the vascular anastomoses can be dramatic and graft- or life-threatening; this presents with sudden hypotension, high drain output and severe pain. More commonly, gradually accumulating peri-nephric haematomas occur due to slow oozing from the transplanted kidney itself. These are more subtle in their presentation, with progressively falling haemoglobin and a collection identified on imaging (5%). Both require return to theatre for haemostasis and removal of haematomas.

Graft thrombosis in the donor renal artery or vein (1%–3%) invariably leads to the loss of the graft as successful operative salvage is rare; causes include technical issues, pro-thrombotic states or severe hypotension. Thrombosis within the recipient's vessels (e.g. secondary to vascular clamp injuries) may lead to limb ischaemia (less than 1%) and require urgent revascularisation.

Major urological complications (MUCs): MUCs are usually defined as including urine leaks from the anastomosis between the transplant ureter and bladder, or stenosis at the same anastomosis. MUCs are rare, 2%–5% in most modern series with routine transplant ureteric stent placement. Both may occur due to technical issues or ischaemia of the distal transplant ureter.

Leaks present with elevated serum creatinine (due to systemic re-absorption of urine), large peri-nephric collections or leakage of clear fluid through the wound. Diagnosis is confirmed by measuring creatinine of the wound or collection fluid (usually >2–5 times the serum creatinine), with anatomical definition provided with a contrast cystogram. Treatment can either be non-operative (insertion of a urethral catheter into the bladder to drain the leak) or operative (return to theatre for washout and re-do anastomosis) depending on surgeon preference and leak size.

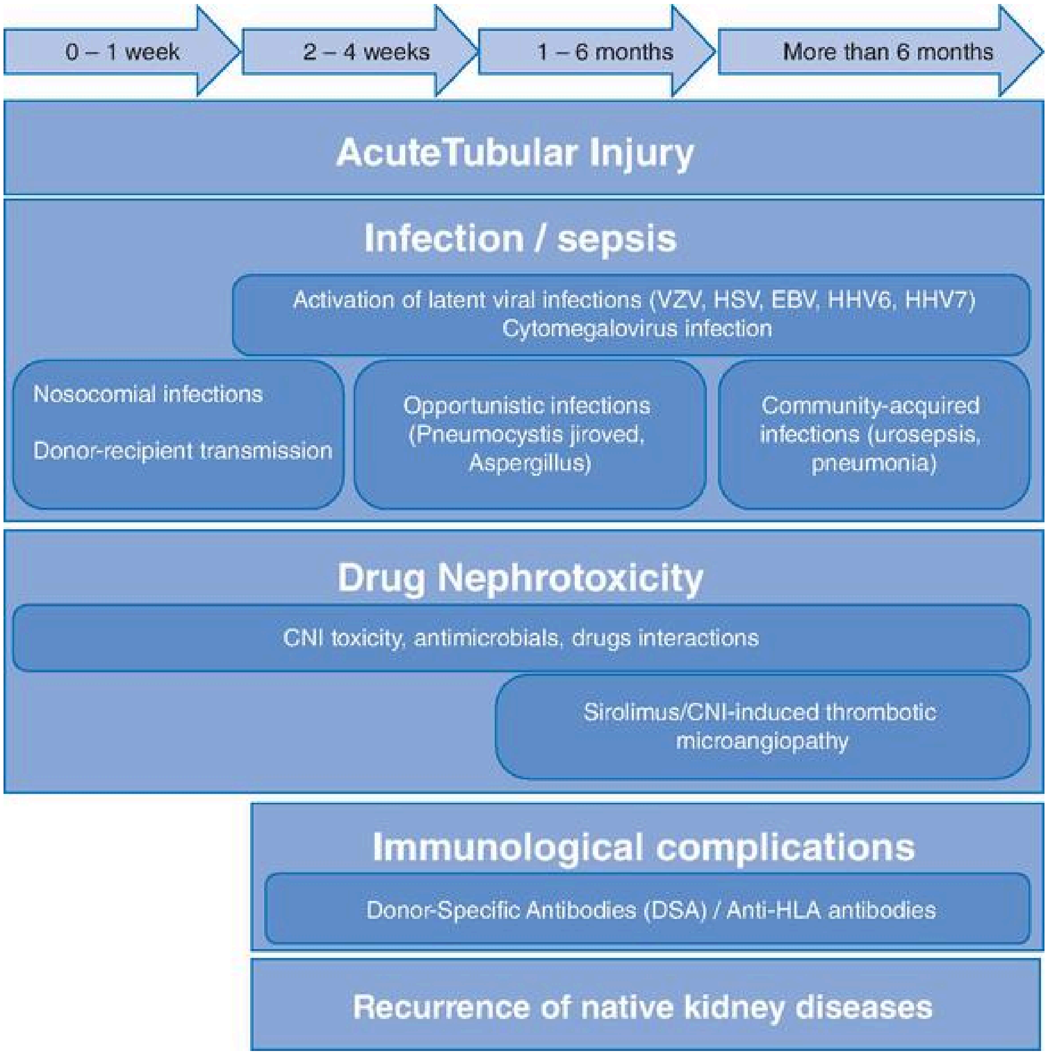
Transplant ureteric stenoses present with graft dysfunction (elevated serum creatinine), with hydronephrosis on ultrasonography and anatomical delineation of the obstruction on nephrostogram imaging. Most stenoses require operative reconstruction after graft function has been stabilised with nephrostomy drainage; placement of long-term stents across the stenosis may be an option in selected patients though this approach risks urinary tract infections.

Acute rejection: Acute rejection describes a range of acute immunological (allo-immune) responses directed against non-self-antigens, usually mismatched class I or class II HLA molecules. Acute rejection most commonly occurs weeks to months post-KT, and is usually classified according to whether the mechanism of rejection is cell-mediated or antibody-mediated and its severity. [67] Acute rejection occurs in approximately 10%–15% of recipients within the first year post-transplant, depending on underlying immunological risk factors (e.g. recipient age, donor-recipient HLA mismatch, previous sensitisation against HLA) and adherence to maintenance immunosuppression.

Close monitoring of recipients in the post-transplant clinic mean that graft dysfunction is usually detected before symptoms of acute rejection can occur (e.g. pain over the graft, bleeding and oligo-anuria). Acute rejection is most commonly diagnosed following detection of graft dysfunction (elevated serum creatinine) with no features of vascular or urological issues on graft ultrasound, and a percutaneous graft biopsy showing features consistent with rejection. Treatment depends on the histological subtype and whether or not donor-specific antibodies have been detected in the recipient's serum (suggesting antibody-mediated rejection – AMR). [68] Mild forms of cell-mediated rejection usually respond to doses of intravenous steroids, whilst more severe forms require T-cell-depleting antibody therapy. AMR is harder to treat, requiring potent immunosuppression with a course of plasma exchange and intravenous immunoglobulin. There is a paucity of randomised controlled trials in this field, and treatment pathways are consequently variable. Recipients undergoing treatment for rejection are at high risk of complications from augmented immunosuppression (e.g. systemic cytomegalovirus (CMV) infection and fungaemia) and require appropriate prophylaxis and close monitoring.

Re-admission to the Intensive Care Unit and Late Complications

Early re-admission: Severe infection is one of the commonest indications for ICU re-admission post-KT, and is often associated with AKI. Fig. 116.1 shows the main 'non-surgical' causes of AKI in KT recipients and their time frame post-transplant. Poor arterial inflow or venous outflow, urinary outflow tract obstructions are usually detected on graft imaging and have been discussed above.



0 – 1 week
2 – 4 weeks
1 – 6 months
More than 6 months
AcuteTubular Injury
Infection / sepsis
Activation of latent viral infections (VZV, HSV, EBV, HHV6, HHV7)
Cytomegalovirus infection
Nosocomial infections
Donor-recipient transmission
Opportunistic infections (Pneumocystis jiroved, Aspergillus)
Community-acquired infections (urosepsis, pneumonia)
Drug Nephrotoxicity
CNI toxicity, antimicrobials, drugs interactions
Sirolimus/CNI-induced thrombotic microangiopathy
Immunological complications
Donor-Specific Antibodies (DSA) / Anti-HLA antibodies
Recurrence of native kidney diseases

The timeline-based diagram outlines causes of kidney allograft dysfunction organised by time intervals following transplant, including 0 to 1 week, 2 to 4 weeks, 1 to 6 months, and more than 6 months. Acute tubular injury is listed at the top, spanning the earliest post-transplant phase. Infection and sepsis are represented as a broad category, including activation of latent viral infections such as V Z V, H S V, E B V, H H V 6, H H V 7, and cytomegalovirus infection. Subcategories include nosocomial infections, donor-recipient transmission, opportunistic infections like Pneumocystis jirovecii and

Aspergillus, and community-acquired infections such as urosepsis and pneumonia. Drug nephrotoxicity is listed next, involving calcineurin inhibitor toxicity, antimicrobial agents, and drug interactions. A subcategory notes sirolimus or calcineurin inhibitor-induced thrombotic microangiopathy. Immunological complications include donor-specific antibodies and anti H L A antibodies. The final section lists the recurrence of native kidney diseases.

FIG. 116.1 Main causes of acute kidney injury in kidney transplantation. *CNI* , calcineurin inhibitors; *EBV* , Epstein–Barr virus; *HHV-6* , human herpesvirus-6; *HHV-7* , human herpesvirus-7; *HLA* , human leukocytes antigens; *VZV* , varicella-zoster virus.

In the early post-transplant period (days to weeks), bacterial wound infections occur in 5%–20% of patients, including superficial and deep infected collections. These usually respond well to antibiotic therapy and collection drainage.

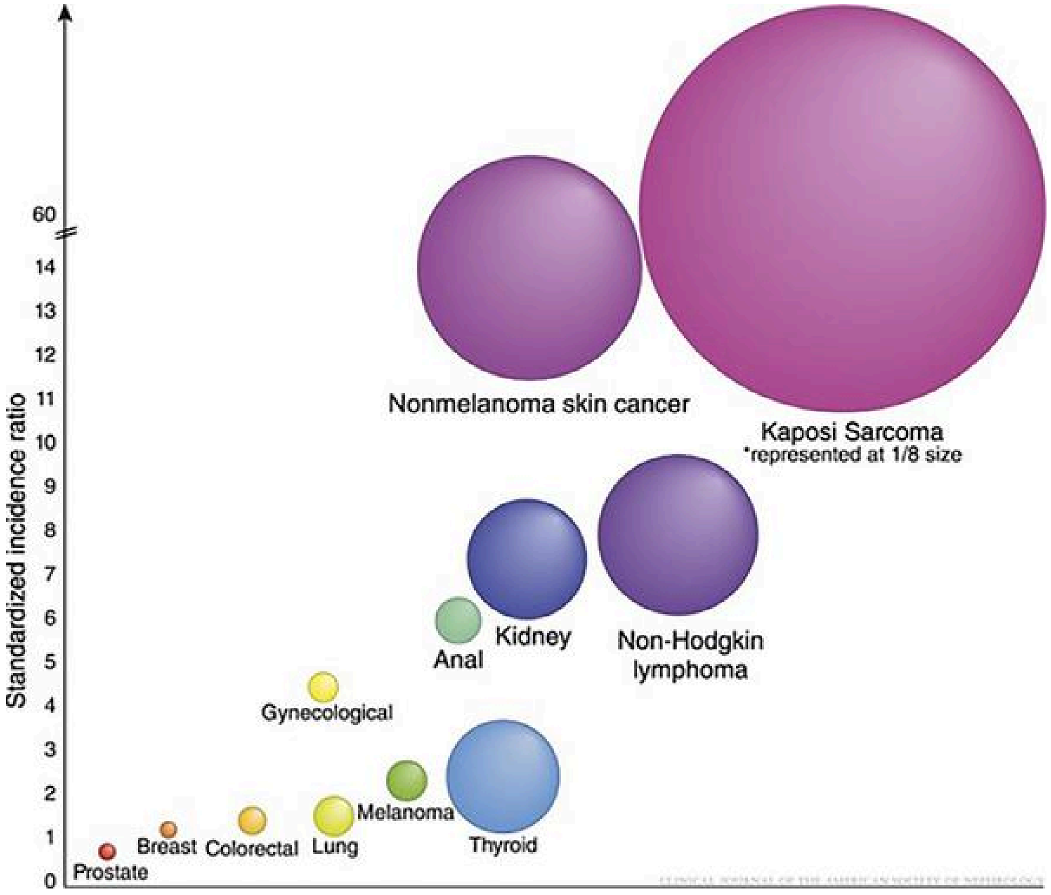
Bacterial urinary tract infections (UTIs) are especially common in the first 4-8 weeks post-transplant due to recent catheterisation, immunosuppression and the presence of the transplant ureteric stent. UTIs are a common cause of severe sepsis and are associated with an impact on graft survival and mortality. Acute graft pyelonephritis is the leading cause of about 20% of sepsis cases, and AKI occurrence is typically linked to the development of septic shock. Enteric bacteria are the primary source of infection in two-thirds of cases with Gram-negative bacilli (e.g. *Escherichia coli*) the prevalent pathogen.

Infection with CMV is most common in the first weeks of month post-transplant. All transplant units will have strategies for minimising CMV infections in at-risk groups, either with regular surveillance or pharmacoprophylaxis (e.g. valganciclovir) or both. CMV infection can manifest as an asymptomatic disease to severe forms with gastrointestinal, pulmonary and kidney involvement, representing an important risk factor for graft dysfunction. CMV infection should be considered in all transplant patients with a fever or significant systemic upset. Mycophenolate mofetil use, lymphocytopenia, anti-thymocyte globulin immunosuppressive regimen, anti-CMV IgG seropositivity of the donor in a seronegative recipient and advanced age are the main risk factors associated with CMV reactivation after KT.

Bacterial chest infections are especially common in the early post-transplant period. Bacterial pneumonia requiring intubation and mechanical ventilation is associated with significant mortality risk (30%–35%). Chest infections occurring weeks to years post-transplant suggest opportunistic infection with atypical organisms due to immunosuppression (e.g. fungi and viruses). *Pneumocystis jirovecii* infection tends to impact recipients late in the post-transplant period once prophylaxis (e.g. with co-trimoxazole) has been discontinued or if increased immunosuppression has been required for rejection episodes. [69]

Late re-admission : Reasons for late ICU re-admissions include severe infections, major cardiac events or the need for complex re-operations (see above). KT is also associated with an increased risk of cancer and this can lead to late re-admission to ICU. Observational data have shown the standard mortality ratios for all cancer types are at least 1.8–1.9 times higher compared with the age- and sex-matched general population (Fig. 116.2). The risk is greatest among those with melanoma, urogenital cancers and non-Hodgkin lymphoma, with an overall risk of cancer-related death exceeding five to ten times that of those without a KT. The three most common post-transplant cancer types include [70] :

- Native kidney (90%) renal cell carcinoma (7 × higher risk)
- Skin cancer, for example, Kaposi sarcoma and non-melanoma cancers (5–8 × higher risk)
- Post-transplant lymphoproliferative disease (PTLD)



The bubble chart plots different cancer types by standardised incidence ratio on the vertical axis. Cancer types are represented as coloured circles of varying size, with larger circles indicating higher incidence. Kaposi sarcoma, shown in the upper right, has the highest standardised incidence ratio, nearly 60 and is noted to be represented at one eighth of its actual size. Nonmelanoma skin cancer follows with a ratio of approximately 14. Kidney, anal, and non-Hodgkin lymphoma cancers cluster around ratios of 6 to 8. Lower on the chart, cancers such as gynaecological, melanoma, lung, colorectal, breast, and prostate appear with ratios below 3. Prostate cancer is represented with the smallest circle at the lowest incidence.

FIG. 116.2 Incidence ratios of different cancer types in recipients of kidney transplants standardised to the age- and sex-matched general population. From Al-Adra D, Al-Qaoud Tala, Fowler K, Wong GI. De novo malignancies after kidney transplantation. *Clin J Am Soc Nephrol* . 2022;17(3):434-443.

Poor immune control of oncogenic viruses in immunosuppressed recipients is a known risk factor for viral-associated cancers such as Kaposi sarcoma (human herpesvirus-8) and PTLD (Epstein–Barr virus).

Paediatric Kidney Transplantation

Kidney transplantation in children and young people is relatively uncommon due to the low rates of ESKD in this population. The commonest causes of ESKD in children are congenital anomalies of the kidney and urinary tract (e.g. renal dysplasia, posterior urethral valves and urinary reflux). The overwhelming majority of children undergoing KT receive organs from adults, and therefore space considerations and the size of arterial inflow and venous outflow vessels are important. Children weighing less than 10 kg may need to wait for the growth of the abdominal compartment and vessels before KT is a feasible option. Other challenges in paediatric KT include the high frequency of complex urological tracts and managing psychological complexities and adherence issues in both the recipients and their parents and caregivers.

Children commonly receive organs from living donors (e.g. parents, other relatives or even grandparents); where this is not an option, deceased donor KT is undertaken. Organs from younger deceased donors (age <50–60 years) with minimal co-morbidities are necessary in order to optimise the chances of long-term graft survival.

Long-term outcomes are good, with patient survival of 95% and death-censored graft survivals of 70%–80% at 10 years. [54] Children and young people often eventually require re-transplantation as they are expected to outlive the lifespan of their grafts. Second, third or even fourth KT is feasible, though is progressively more challenging, both technically and immunologically.

Pancreas Transplantation

Introduction

Pancreas transplantation (PT) can be performed as either solid organ transplantation (the combined exocrine and endocrine portions of the pancreas with an attached segment of donor duodenum) or as islet transplantation after ex-situ enzymatic separation of the pancreas. This chapter deals only with solid organ PT, which is far more common than islet transplantation and more likely to come to the attention of intensive care practitioners. Hereafter, solid organ pancreas transplantation is referred to as ‘pancreas transplantation’.

PT is performed only 150–200 times per year in the United Kingdom, reflecting the complexity of the surgery, the incidence of early post-transplant morbidity and the increasing array of treatment options available to patients with insulin-dependent diabetes mellitus. Short- and long-term outcomes after PT depend on the type of PT performed, with better outcomes if the pancreas is implanted along with a kidney from the same donor (simultaneous pancreas-kidney [SPK] transplantation). In SPK transplant recipients, patient survival at one year is 95%–96% with pancreas death-censored graft survivals of 85%–90%, and 10-year patent and graft survivals of 75%–85% and 65%–75%, respectively. [54]

SPK transplant recipients with a functioning pancreas at three months after transplantation have superior outcomes for kidney graft and patient survival than kidney transplant alone, after adjusting made for recipient, donor and transplant factors. [71] However, SPK transplantation is associated with higher perioperative morbidity and mortality compared to KT alone.

Candidate Selection and Work-Up

The majority of PTs are performed as SPK transplants in patients with insulin-dependent diabetes and ESKD due to diabetic nephropathy. There are multiple treatment options for patients with ESKD and insulin-dependent diabetes mellitus, and these patients require careful assessment and exploration of options.

Assessment pathways are often more detailed than those for KT due to the additional co-morbidities associated with long-term diabetes and the magnitude of the operation. Indications vary according to the type of PT (Table 116.5). Contraindications are similar to those of KT (Table 116.2). PT work-up pathways vary between units, but almost always include a form of cardiac imaging and stress testing, imaging of iliac vessels, as well as the virological and immunological blood tests that are required for KT (Table 116.3).

Table 116.5

Indications for PT, by type of transplant

SIMULTANEOUS PANCREAS-KIDNEY (SPK) Transplant
Insulin-dependent type 1 or type 2 [a] diabetes mellitus with end-stage renal disease [b]
PANCREAS TRANSPLANT ALONE
Insulin-dependent type 1 or type 2 [a] diabetes mellitus, with adequate renal function (usually >40 mL/min/1.73 m^2), and with at least two severe hypoglycaemic episodes within the last 24 months
PANCREAS AFTER KIDNEY (PAK) TRANSPLANT
Insulin-dependent type 1 or type 2 [a] diabetes mellitus, with adequate renal function (usually >40 mL/min/1.73 m^2), after previous kidney transplantation

Adapted from UK national policies (https://www.odt.nhs.uk/transplantation/tools-policies-and-guidance/policies-and-guidance/).

[a] Recipient BMI must be <30 kg/m^2 in those with type II diabetes mellitus.

[b] eGFR <20 mL/min/1.73 m^2 in UK listing criteria.

Donor Options

Although a small number of pancreas transplants from living donors have been performed in the US and Japan, the overwhelming majority of PTs are from deceased donors. Because of the propensity of endocrine pancreas function to decline with age, and for reperfusion pancreatitis to occur as a result of fat infiltration, deceased pancreas donors are generally young (<50–60 years of age) and slim (BMI <30–32 kg/m^2). Both donation after brain death (DBD) and donation after circulatory death (DCD) donors can be utilised for PT, though DBD donors are more commonly used.[72] The pancreas should ideally be implanted with a cold ischaemic time of less than 10–12 hours.

Peri-Operative Issues

Operative technique: The blood supply to the pancreas is complex, and arterial inflow to the pancreas needs to be reconstructed on the back table using a donor iliac arterial ‘Y’ graft. Implantation techniques vary, but most surgeons prefer to place the pancreas intraperitoneally, after extensive mobilisation of the right colon and duodenum and clamping of major blood vessels. PT alone is usually of 2–4 hours’ duration whilst SPK transplantation can take 6–12 hours. Pancreatic venous drainage is usually directly into the IVC, and arterial inflow via the right common iliac artery. Exocrine secretions are most commonly drained into the recipient’s small bowel via a hand-sewn anastomosis. Many other technical variations exist, including venous outflow to the portal venous system via the superior mesenteric vein, and exocrine drainage directly into the bladder. The pancreas is a highly vascular organ, and it is not uncommon for 500–1000 mL of blood to be lost during pancreas reperfusion. In SPK transplantation, the kidney is most commonly implanted into the left iliac fossa (external iliac artery and vein) with a transplant ureteric anastomosis to the bladder over a stent.

It is important that critical care staff read the operative note so that the anatomical placement of the pancreas (and kidney) and the drainage of secretions is understood.

Intra-operative monitoring: Given the duration of the operation, the multiple co-morbidities of many recipients, and the expected blood loss, most anaesthetists would place two large-bore peripheral cannulae, an arterial line and a central venous line. In SPK transplantation, vascular access is required for haemofiltration in the ICU in case the kidney graft develops DGF; this access can either be through a temporary dialysis line (e.g. Vascath) or an existing long-term dialysis line (e.g. Permacath). A bladder catheter is needed in those who already pass urine or who are expected to post-operatively.

Fluid replacement strategies : Intra-operatively, fluid losses are generally replaced with balanced crystalloids, and with packed red blood cells to maintain Hb >7.0 g/dL. Vascular depletion and hypotension should be avoided due to the risks of myocardial ischaemia and graft vascular thromboses in this multi co-morbid population. Each transplant unit will have its own fluid replacement policy intra-operatively and post-operatively and these should be followed closely. The evidence base underpinning these approaches is acknowledged to be sparse.

Post-operative care: Many centres undertaking SPK transplantation routinely admit patients to ICU post-transplant due to the length of the operation, the high risk of significant early complications (see later), and the need for intensive monitoring and fluid balance.

All pancreas transplant recipients require frequent blood glucose monitoring to assess pancreas graft function in the early post-operative period. It is expected that the overwhelming majority of recipients will be free of the need for exogenous insulin treatment by the end of the transplant. Blood glucose consistently >10 mmol/L should prompt further investigations to identify causes of pancreas graft dysfunction (e.g. contrast-enhanced CT scanning to identify graft thrombosis). On occasion, re-laparotomy will be needed. It is important that ICU staff contact the transplant surgical team early if there are any concerns about pancreas graft dysfunction; avoid treating hyperglycaemia with exogenous insulin as this will obviate pancreas graft functional assessment.

Immunosuppressive strategies: Induction immunosuppression is most commonly with a T-cell depleting agent (anti-thymocyte globulin or alemtuzumab), and high-dose corticosteroids; maintenance immunosuppression is usually with oral tacrolimus and mycophenolate mofetil, though many variations exist. In general, many units favour steroid avoidance strategies to minimise diabetogenic effects. Each unit will have its own immunosuppression policy which should be followed closely.

Early Post-Transplant Issues and Complications

Delayed pancreas graft function: The transplanted pancreas graft usually begins to work within minutes of reperfusion in the recipient, leading to normoglycaemia within hours. The ongoing need for exogenous insulin therapy within the first week post-transplant can be defined as pancreas DGF but is rare (<10%). Other causes for post-transplant insulin-dependence must be excluded (e.g. graft thrombosis).

Primary pancreas non-function: Failure of the pancreas graft to ever work occurs in <5% of transplants and is most commonly due to early graft thrombosis (arterial or thrombosis) or severe bleeding requiring graft pancreatectomy. Severe acute pancreas rejection leading to PNF is rare.

Vascular complications: Bleeding can be severe and may be life-threatening. Injuries from vascular clamps leading to limb ischaemia (1%–2%) are more common than in KT due to the vasculopathy associated with long-term diabetes and because two organs are implanted in SPK transplantation.

Thrombosis of the transplanted pancreas is approximately twice as common in PT than KT (5%–10%) because of the relatively low blood flow through the pancreas. As with KT, thrombosis of the pancreas almost invariably leads to the need for graft removal. Thrombosis usually presents within the first week post-transplant with rapidly rising blood glucose, and localisation of the thrombus on contrast-enhanced CT scanning.

Other major complications: The intraperitoneal placement of the pancreas, coupled with the need for an anastomosis to the recipient's small bowel means that enteric complications are common (10%–20%). These include prolonged ileus, mechanical bowel obstruction and leaks from the enteric anastomosis. Leakage of enzyme-rich gastrointestinal contents can lead to peritonitis requiring re-laparotomy, washout ± graft pancreatectomy. Sterile or infected peri-pancreatic collections are common (15%–20%), as is post-reperfusion graft pancreatitis; these may require percutaneous drainage under radiological guidance, or re-laparotomy. Overall, re-laparotomies are needed in 20%–30% of patients after PT.

Acute Pancreas Rejection

As with KT, pancreas graft rejection can be classified according to type (cell-mediated or AMR) and severity. Rejection should be considered in those with elevated blood glucose, HbA_{1c}, or exocrine pancreatic markers (serum amylase or lipase); concomitant kidney graft rejection can occur in those with SPK transplants. Severe pancreas rejection can present with abdominal pain and raised inflammatory markers, though this is rare. The gold standard for diagnosis is percutaneous pancreas biopsy, and treatment is dependent on rejection type and severity. The prognosis of pancreas graft rejection is generally worse than that of kidney rejection as it is often diagnosed later in the disease process and seems more resistant to therapies.

Re-admission to the Intensive Care Unit and Late Complications

There are multiple early (within 60 days of transplantation) complications of SPK transplantation that can all contribute to the need for return to theatre and also re-admission to ICU including graft pancreatitis, intra-abdominal peri-pancreatic infection or abscesses, graft-vessel thrombosis, gastrointestinal anastomotic leak leading to peritonitis, intra-abdominal haemorrhage, and graft thrombosis requiring graft pancreatectomy.

The 10-year cardiovascular complication rate has been reported at 25% in SPK transplant recipients. This is in spite of effective glycemia control following PT, which delays microvascular progression and its complications improving survival in diabetic patients. Cardiovascular co-morbidity is the main factor that threatens the long-term survival of pancreas transplant patients.[73]

Late Re-Admission to the Intensive Care Unit

There are several late complications associated with SPK transplantation and these can be related to the pancreas, bowel or vasculature and some will result in re-admission to ICU. Allograft parenchymal complications include enteric complications (e.g. small bowel obstruction), vascular complications (e.g. arterial or venous pseudoaneurysms) and malignancy. Tumours related to viral infections such as PTLD can develop. Infections after PT follow a pattern, occurring at specific time points after transplantation:

- **Month 1** after transplantation, bacterial infections derived from the surgical procedure are common.
- **Month 2–6** , the main risk factor is immunosuppression and patients develop opportunistic infections and there can be reactivation of latent viruses (e.g. CMV, hepatitis B and C viruses, EBV and varicella-zoster virus). There is also the risk of opportunistic bacteria, which can include *Pneumocystis jiroveci* pneumonia, nocardia, *Listeria monocytogenes* , *Toxoplasma gondii* or fungal infections.
- **After 6 months,** in patients with good allograft function, the majority of infections are those acquired in the community, similar to the general population, although opportunistic infections may also occur.

Paediatric Pancreas Transplantation

PT in those aged less than 18 years is very rare; ESKD due to diabetic nephropathy takes 10-15 years to develop and is therefore almost exclusively a disease of adults. children and young people with recurrent severe hypoglycaemic events almost always have major psychosocial issues that need to be addressed before PT is a viable option.

Heart transplantation

Priya Nair, Paul Jansz and Peter Macdonald

Introduction

The first human-to-human heart transplant was performed in 1967 by Christiaan Barnard at Groote Schuur Hospital in South Africa. This was followed by other centres across the world commencing transplant programmes. Initial results were poor due to rejection leading to suspension of cardiac transplant activity at the time, but the discovery of cyclosporine and its introduction into clinical transplantation in the late 1970s led to renewed interest with a rapid growth in transplant activity throughout the 1980s. Currently, it is estimated that approximately 5000 transplants are performed each year in over 300 countries. The survival rate after heart transplantation has improved steadily over the last two decades and currently approaches 85% at 1 year, 75% at 5 years and 56% at 10 years. Median survival is 12 years. Heart transplantation is now well established as the most effective treatment available for end-stage heart failure.[1]

Heart transplantation is limited by donor organ availability. Historically, the vast majority of deceased donors for heart transplantation were brain dead (DBD). More recently, donation after circulatory determination of death (DCDD) has re-emerged as an important source of donor hearts. Distant procurement and successful heart transplantation from DCDD donors have now been reported by multiple centres using normothermic ex vivo perfusion with a randomised multi-centre trial reporting excellent post-transplant survival of DCDD heart transplant recipients comparable to that of contemporaneous DBD heart transplant recipients.[2,3]

Virtually all of the improvement in heart transplant survival over the last 20 years has been during the first few months after transplantation. [1] The improvement in survival can be explained by a number of factors, including advances in immunosuppressive therapy with fewer deaths due to rejection or infection, and better patient selection.

The Potential Heart Donor

Of all organs retrieved, the heart is the one most susceptible to the multiple insults that occur during brain death and the subsequent events that occur during donor organ retrieval and transplantation. Studies involving repeated echocardiographic examination of the brain-dead donor have revealed that left ventricular systolic dysfunction is common which often improves together with haemodynamic status after a period of aggressive donor management. [4]

In addition to its susceptibility to the adverse consequences of brain death, the heart is the donor organ least tolerant to the obligatory ischaemia reperfusion injury (IRI) that occurs during retrieval and implantation. Data from the International Society of Heart and Lung Transplantation (ISHLT) Registry indicates that as the donor heart ischaemic time (the time from cross-clamp of the aorta in the donor to release of the aortic cross-clamp in the recipient) increases beyond 3 hours there is a progressive increase in the mortality rate at 1-year post-transplant. [1] Normothermic and hypothermic machine perfusion of donor hearts provide oxygen delivery to the donor heart during transport thereby dramatically reducing the cold ischaemic time and potentially allowing a marked increase in the transport time between donor and recipient hospitals. [5, 6]

Donor Eligibility Criteria

Donor eligibility criteria vary between jurisdictions. Those that are currently utilised in Australia and New Zealand are summarised in Table 117.1 . [7] As indicated, donors are subdivided into standard criteria and higher-risk donors based on a range of donor characteristics, which, if present, are associated with an increased risk of graft failure and lower survival. Echocardiographic assessment of the donor’s heart is recommended in all cases. Donor heart dysfunction does not necessarily imply pre-existing disease but is associated with an increased risk of primary graft failure (PGF).[8,9] In donors with suspected coronary artery disease, coronary angiography is recommended, where possible.

Table 117.1

Standard versus higher-risk criteria for donor hearts

DONOR PARAMETER	STANDARD CRITERIA	HIGHER-RISK CRITERIA (MARGINAL)
Age	<50 years	>50 years
Donor cardiac history	Nil	Pre-existing disease
Donor co-morbidities	Absent	Hepatitis B, C
Echocardiography [a]	Normal	Global dysfunction (LVEF <50%) Major regional wall motion abnormality Left ventricular hypertrophy (LV wall >13 mm)
Coronary angiography [a]	Normal or non-occlusive disease	Occlusive coronary artery disease
Haemodynamic status	Stable	Unstable with high CVP (and/or PAoP) and low BP
Inotropic support	Low	High (>0.2 ug/kg/min of noradrenaline or equivalent)
Ischaemic time	<6 h	>6 h

[a] Severe abnormalities will generally result in non-use of the organ.

BP , Blood pressure; *CVP* , central venous pressure; *LV* , left ventricle; *LVEF* , left ventricular ejection fraction; *PAop* , pulmonary artery occlusion pressure.

Donor Management

Management of the multiorgan donor has been discussed in Chapter 115 . However, hormonal resuscitation is of specific relevance to cardiac transplantation. Vasopressin has been administered to the brain-dead donor often as part of a multi-hormonal cocktail usually with high-dose steroids and thyroid hormone, resulting in the sparing of catecholamines, such as noradrenaline, which improves the suitability of the donor heart. [10] Use of other hormonal therapies, particularly thyroid hormone administration is controversial. In a systematic review, Macdonald and co-authors identified 16 case series and 7 randomised controlled trials (RCTs) of thyroid hormone administration to brain-dead potential organ donors. [11] Whereas all case series reported a beneficial effect of thyroid hormone administration on a range of outcomes including donor haemodynamic stability and donor heart utilisation, none of the RCTs reported any benefit. Despite this controversy, thyroid hormone in conjunction with other hormonal therapies has been recommended as part of an aggressive management protocol for the potential cardiothoracic donor and is currently incorporated into the UNOS Critical Pathway for the Organ Donor.

Donor Heart Preservation

The most common method of donor heart preservation involves cardioplegia with a cold hyperkalaemic crystalloid solution and then static cold storage (SCS) in a preservation solution in an ice chest during transport between donor and recipient hospitals. There are multiple preservation solutions in use reflecting a lack of consensus regarding the optimal composition of these solutions. [12] All provide good preservation for up to 3 hours but beyond this, there is a steady increase in the rate of PGF and mortality. This has led to a renewed interest in the use of ex vivo machine perfusion (MP)- both normothermic (NMP) and hypothermic (HMP) to transport hearts between donor and recipient hospitals. These provide oxygen to the donor’s heart and restore aerobic metabolism, thereby minimising the ischaemic insult to the donor’s heart. Based on currently available data, MP is non-inferior to standard SCS. Additionally, single-centre studies suggest that NMP could preserve the hearts of donors outside standard acceptability criteria and DCDD hearts with comparable results to SCS. Finally, HMP is theoretically safer and simpler to use than NMP. [13]

Selection of Patients for Heart Transplantation

Eligibility criteria for heart transplantation have been extensively reviewed elsewhere and recently revised. [14] Heart transplantation is restricted to patients with end-stage heart disease who have exhausted all alternative therapies. Most patients have long-standing heart failure due either to ischaemic heart disease or some form of cardiomyopathy. [1] A substantial proportion of these patients require long-term mechanical circulatory support (MCS) with ventricular assist devices (VADs) – so-called bridge to transplant – and currently between 30% and 50% of wait-listed patients are on such support. [1] There has been a dramatic evolution in the design – from large pulsatile pumps to small continuous flow devices – which have proven to be far more durable. Two-year survival rates for persons supported on continuous flow devices are now better than 80%. [15] Patients on long-term VAD support are managed as outpatients and undergo cardiac rehabilitation to optimise their physical condition prior to transplant surgery. VAD support has also been used in patients who are otherwise marginal candidates for heart transplantation due to factors such as renal impairment and pulmonary hypertension – the so-called ‘bridge to decision’. Long-term support has been associated with reversal of these co-morbidities in several case series. [16], [17]

Although historically, heart transplantation has been restricted to younger patients; older patients are undergoing heart transplantation with acceptable outcomes with appropriate case selection. [18] Both advanced age and end-stage heart failure may be associated with physical frailty, which has been shown to be an independent predictor of mortality both before and after heart transplantation and is associated with increased morbidity with heart transplantation. [19] Routine frailty screening is now recommended for all patients referred for heart transplantation. [20]

Severe, irreversible pulmonary hypertension with a pulmonary vascular resistance (PVR) greater than 6–8 Wood units, which is unresponsive to pulmonary vasodilators remains one of the few contraindications. This is related to the excessive afterload placed on the donor heart and the possibility of acute right ventricular failure in the recipient. The degree of responsiveness of the pulmonary vasculature is key for patient selection. Some centres consider severe pulmonary hypertension to be a relative contraindication only and consider patients after medical therapy with pulmonary vasodilators and right ventricular inotropes in an outpatient setting and/or subject them to combined heart-lung transplantation. [21] Another approach which has been shown to reverse fixed severe pulmonary hypertension secondary to left heart disease is implantation of a left VAD with or without temporary right ventricular support. [22]

A small proportion of patients who require consideration for transplantation present acutely in cardiogenic shock following acute myocardial infarction, cardiac surgery (post-cardiotomy) or fulminant myocarditis. Short-term survival of these patients is usually dependent on acute MCS, for example with veno-arterial extracorporeal membrane oxygenation (VA-ECMO). Following the stabilisation of vital organ function and the establishment that the heart will not recover, these patients may be transitioned to a VAD for longer-term support (so-called ‘bridge to bridge’). [23] Alternatively, they may be listed for urgent heart transplantation. [24]

Heart Transplant Surgery

Orthotopic heart transplantation is performed orthotopically by excising the native heart and implanting the donor heart in its place. This technique involves anastomosis of the left and right donor atria to the back walls of the corresponding recipient atria containing the central connections of the vena cava and pulmonary veins. An alternative surgical technique involves bicaval anastomosis. The right atrial bicaval anastomosis can be performed alone or in conjunction with anastomosis at the level of the pulmonary veins rather than at the level of the left atrium. The proposed advantages of this technique include better preservation of atrial anatomy and function with a reduced risk of atrial thrombosis, atrial arrhythmias and atrio-ventricular (AV) valve regurgitation during long-term follow-up. A recent systematic review showed that the bicaval technique has more favourable early and late outcomes when compared with the bi-atrial technique. [25]

Once the atrial, pulmonary artery and aortic connections are completed, vents are placed in the left ventricle (LV) and the aorta, the heart is de-aired and the cross-clamp is released. Temporary pacing wires are placed onto the heart and the heart is allowed a period of reperfusion while on cardiopulmonary bypass (CPB). The duration of the unloaded reperfusion varies and is related to the ischaemic time. A heart that has endured an ischaemic time (from cross-clamp in the donor to reperfusion in the recipient) of 4 hours may be given up to 1 hour of reperfusion before commencing separation from CPB and allowing the heart to work. Separation from CPB and the completion of the procedure needs to proceed carefully as the transplanted heart, in particular the right ventricle (RV), is prone to acute failure.

Post-Transplant Management

Immediate Post-Transplant Care and Monitoring

In the stable uncomplicated case after transfer to the intensive care unit (ICU), the patient is extubated usually after 6–8 hours. Routine monitoring includes electrocardiogram (ECG), arterial line, pulmonary artery catheter (PAC), central venous (CVP) line and urinary catheter. [26] In some centres, separate left atrial and CVP lines have been used instead of the PAC; however, the latter has the advantage of providing pulmonary artery pressures (PAPs) and a calculated measure of the PVR. Pericardial, mediastinal and one or more pleural drains will be in place.

Physiology of the Transplanted Heart

The rhythm of the transplanted heart in the immediate post-transplant period is highly variable. While there may be early establishment of sinus rhythm, often the heart is profoundly bradycardic during the first few days. Typically, the sinus rate increases steadily over the first 1 to 2 weeks post-transplant and eventually stabilises at a resting rate between 90 and 100 beats per minute. Surgery performed with bi-atrial anastomosis may result in the appearance of dual P waves on the ECG arising from the donor and recipient atria. This is eliminated in the case of bicaval anastomosis.

As the heart is denervated, the effect of drugs is altered (Table 117.2). Those that act by augmenting or inhibiting vagal efferent activity (e.g. digoxin and atropine) will have no effect on the transplanted heart. The transplanted heart is often ‘stunned’ by the IRI that occurs in the first 24 hours after transplantation. During this period the heart often demonstrates diastolic dysfunction with a restrictive filling pattern, which may persist for days. Persistent diastolic dysfunction beyond the first-week post-transplant suggests the development of acute rejection.

Table 117.2

Effect of drugs on denervated heart

DRUG	EFFECT ON THE HEART	MECHANISM
Digoxin	Increased contractility; Minimal effect on AV node	Direct myocardial effect; denervation
Atropine	None	Denervation
Adrenaline	Increased contractility; increased chronotropy	Denervation hypersensitivity
Noradrenaline	Increased contractility; increased chronotropy	Denervation hypersensitivity
Isoprenaline	Normal increase in contractility; normal increase in chronotropy	No neuronal uptake
Hydralazine	No reflex tachycardia	Denervation
Beta-blockers	Increased antagonist effect	Denervation
Verapamil	Blocks AV node	Direct effect
Nifedipine	No reflex tachycardia	Denervation

AV , Atrio-ventricular.

Heart transplant recipients often have a large pericardial space which has adapted to prior cardiomegaly for a much smaller donor heart. As a result, recipients with pericardial effusion may remain haemodynamically stable. Up to 30% of heart transplant recipients develop large pericardial effusions. The typical echocardiographic findings of systolic right atrial (RA) collapse followed by diastolic RV collapse that is seen in concentric pericardial effusion may not be present. [27]

Cardiac Rhythm and Pacing

AV sequential pacing with temporary pacing wires is routine in the immediate post-transplant period. Filling pressures of 10–15 mm Hg may be required to ensure adequate diastolic filling, but due to the impairment of the Frank–Starling mechanism (increased stroke volume with raised preload) from IRI, AV sequential pacing at rates up to 110 beats per minute may be required to maintain a normal cardiac output and stable arterial pressure. During the first week, the sinus rhythm of the transplanted heart usually increases steadily, and pacing is weaned and suspended when a stable sinus rhythm above 60 beats per minute is established. Administration of amiodarone to the recipient prior to transplantation may delay sinus node recovery. Between 5% and 10% of transplanted hearts remain profoundly bradycardic and require implantation of a permanent pacemaker, usually after 3 weeks, which is allowed for the recovery of sinus rhythm. [28]

Atrial fibrillation is less common than after other forms of cardiac surgery possibly due to better preservation of atrial myocardium. Atrial flutter occurring beyond the first week post-transplant is suggestive of acute rejection and should prompt endomyocardial biopsy. If pacing wires are still present, they can be used to attempt atrial overdrive pacing (AOD). Alternatively, AOD pacing can be performed at the completion of the biopsy procedure. Ventricular tachyarrhythmias are very uncommon and are usually observed in the setting of severe PGF.

Vasoactive Agents

The goal in the immediate post-operative phase is to achieve an adequate cardiac output and perfusion pressure to preserve organ function. Due to the autonomic denervation, the transplanted heart is preload dependent and stroke volume depends on LV end diastolic volume and usually requires some level of chronotropic and inotropic support both for the RV and LV. At the same time, however, it is important to consider the vulnerability of the graft from IRI causing both systolic and diastolic dysfunction, and the requirement of escalating doses of catecholamines, which inevitably increase myocardial oxygen requirement, which may signify the need for MCS in the form of intra-aortic balloon counter pulsation or VA-ECMO. Some risk factors for impaired diastolic function in the early post-operative period include donor heart LV hypertrophy with LV wall thickness >14 mm, and prolonged ischaemia times of >240 minutes. [29]

The RV is particularly vulnerable in the transplanted heart for a number of potential reasons including fixed pulmonary hypertension in the recipient, blood transfusion, poor donor heart preservation, poor RV protection during allograft implantation, ischaemia from right coronary air embolism, significant donor-recipient size mismatch and overdistension of the RV on weaning from CPB. [29] Specific attention therefore to maintaining RV perfusion pressure (with an adequate arterial BP and avoiding RV overdistension with fluid), appropriate pacing and inotrope strategies and minimising RV afterload [30] with selective (inhaled nitric oxide and inhaled prostacyclin) or non-selective (e.g. nitrates and milrinone) pulmonary vasodilators and metabolic optimisation are relevant considerations.

Isoprenaline has been used traditionally in the immediate post-transplant phase based on its chronotropic, inotropic and pulmonary vasodilator properties. In the absence of large trials, it is unclear whether these properties make it any more effective than alternative inotropic agents such as adrenaline, dobutamine or milrinone. The lowest effective doses of inotropic medications should be used and weaned as tolerated over the first 3-to-5 days. [26] Usually, inotropic and vasopressor support can be weaned within the first 48–72 hours as the donor heart recovers.

Vasoplegia (profound systemic vasodilatation in the absence of low cardiac output, unresponsive to volume administration) is more common (13%–58%) in patients undergoing heart transplant compared with those undergoing non-transplant cardiac surgery (5%–29%) and occurs generally within 6 hours post-CPB. A number of possible mechanisms including a sustained inflammatory state, nitric oxide synthase activation and relative or absolute deficiency of arginine-vasopressin have been suggested. The contributory factors to vasoplegia in OHT include high body mass index, diabetes mellitus, endothelial injury, pre-operative medical therapy for heart failure (with calcium channel blocker, angiotensin-converting enzyme inhibitor and angiotensin-receptor blocker), pre-operative inodilator (dobutamine and milrinone) therapy, pre-operative LVAD or ECMO support, prolonged CPB time, hypothermia, total cardioplegic volume infused and haemolysis.[29] Noradrenaline and vasopressin (up to 0.1 U/min) are recommended as first-line agents. Vasopressin may have a noradrenaline-sparing effect and additionally has less effect on PVR. Studies on angiotensin-II as a vasopressor are under way but there is currently insufficient evidence to make a recommendation. Both methylene blue (1–2 mg/kg) and hydroxocobalamin (5G over 15 mins) have been used to treat catecholamine-resistant vasoplegia as second-line agents. They act by reducing the release of NO. Therefore there is the possibility of increasing PVR and PAP when methylene blue is administered. Contraindications to methylene blue include glucose-6-phosphate deficiency and pre-operative serotoninergic therapy.[29, 31]

Minimising inflammatory response by removing inflammatory mediators from the circulation through cytokine haemadsorption during and soon after CPB has been explored to reduce the severity of vasoplegia. Studies looking into this are small[32-34] and further studies are required before a recommendation can be made.

Prior to heart transplant, the recipient’s arterial circulation in many cases has adapted to chronic hypotension with systolic blood pressures in the range of 80–90 mm Hg. Replacement with a healthy donor heart often leads to a rapid increase in blood pressure in the recipient as the donor heart regains normal function over the first few days post-transplant. This may be further exacerbated by the introduction of calcineurin inhibitors (CNIs), which can cause renal and systemic vasoconstriction. Systolic blood pressures in excess of 140 mm Hg in the first weeks after post-transplant may result in hypertensive encephalopathy, which may manifest as headache, drowsiness and seizures. Therefore strict control of blood pressure is required during this early post-operative phase.

Respiratory Management

As mentioned, in uncomplicated cases extubation is generally achieved in the first few hours. An appreciation of cardiopulmonary interactions is especially relevant in these patients. Minimising PVR by ventilating at appropriate lung volumes (close to functional residual capacity), optimising oxygenation and minimising acidosis are important considerations. Similarly, the effects of increase in systemic preload and afterload with extubation should be anticipated in patients with unstable graft function.

Fluid Therapy and Renal Monitoring

Judicious attention to volume status is a key component of early ICU management. This is due to the vulnerable state of the RV and its sensitivity to large-volume boluses, which could result in a spiral of progressive RV dilatation and dysfunction. Similarly, blood and product therapy should be rationalised owing to their potential adverse effect on PVR. Patients who have had a prior left ventricular assist device are more likely to suffer bleeding due to extensive dissection and anticoagulant therapy and use of viscoelastic tests (such as thromboelastometry) to guide haemostatic therapy may be of benefit.

The reported incidence of acute kidney injury (AKI) following heart transplantation varies between 14% and 83% and reported rates of renal replacement therapy (RRT) range from 5% to 46%. [35] The consequences of developing AKI can be severe due to complex cardiorenal interactions and the impact on inflammatory cascades amongst numerous other effects. It has been shown that severe renal impairment in the early post-operative period is associated with increased early and late mortality, mechanical ventilation duration, length of stay and healthcare-associated costs. The majority of these patients do not require long-term RRT. Risk factors reported for the development of AKI in the immediate post-transplant phase include age, increased BMI, reduced GFR pre-operatively, prolonged operation and CPB time, vasopressor dose and requirement for MCS. [35-37] Additionally, consideration of reduction of CNI dose or alternative immunosuppression may be required.

Immunosuppression

Maintenance immunosuppression initially involves the administration of three drugs in combination – high-dose corticosteroids, an anti-metabolite (mycophenolate mofetil or azathioprine) and a CNI (cyclosporine or tacrolimus). Some transplant units also use *induction* therapy, either a T cell cytolytic agent (e.g. anti-thymocyte globulin-ATG) or an antibody that specifically blocks the activated Interleukin (IL)2 receptor (e.g. basiliximab). The T cell cytolytic agents are not only more potent immunosuppressive agents but also are associated with more side effects related to the acute destruction of large numbers of T cells in the circulation (the so-called 'cytokine release syndrome'). Their use is associated with an increased risk of viral and fungal infections as well as later development of post-transplant lymphoproliferative disease (PTLD). The IL2R inhibitors have a much better side effect profile and their use is not associated with any increased risk of infection or PTLD.[26], [38]

Infection Prophylaxis

With currently used immunosuppressive drug protocols, the risk of infection is relatively low. Prophylactic antibiotic therapy, often comprising of a cephalosporin administered intravenously over the first 24 hours is routine; however, the choice of antibiotic may vary if the recipient is known to be colonised with multi-resistant organisms. Pneumocystis prophylaxis in the form of oral co-trimoxazole is commenced in the first-week post-transplantation and continued indefinitely. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first 2 weeks post-transplant. Prophylaxis against other fungi particularly Aspergillus varies and depends on local resistance patterns. Inhaled amphotericin for the first week followed by oral itraconazole for 3 months is one approach. In the event of a cytomegalovirus (CMV) mismatch (CMV-positive donor with CMV-negative recipient), oral valganciclovir is administered for the first 3–6 months. Some centres also administer valganciclovir to CMV-positive recipients.[26]

Complications

Primary Graft Failure

PGF is a syndrome in which the transplanted heart fails to meet the circulatory requirements of the recipient in the immediate post-transplant period as a consequence of either single or bi-ventricular dysfunction (Table 117.3). It is manifested as hypotension and low cardiac output in the presence of adequate filling pressures. [9] It accounts for approximately 40% of all deaths within the first month. When defined as the need for high-dose inotropes or mechanical assist devices in the immediate post-transplant period, most investigators have reported incidence rates of 10%–20% or higher. Standardised diagnostic criteria for PGF have now been developed and are listed in Table 117.4 . A number of risk factors, which are donor-related, recipient-related and procedure-related, have been identified (Table 117.5).

Table 117.3

IABP , Intra-aortic balloon pump; *PTLD,* post-transplant lymphoproliferative disorder; *RIFLE,* risk, injury, failure, loss, end-stage kidney disease; *RRT,* renal replacement therapy; *TR,* tricuspid regurgitation; *VAD,* ventricular assist devices; *VA-ECMO,* veno-arterial extracorporeal membrane oxygenation.

Table 117.4

International society for heart and lung transplantation diagnostic criteria and grading of primary graft dysfunction after heart transplantation

PRESENCE OF	EVIDENCED BY
Appropriate time frame	Onset <24 h post-transplantation
Ventricular systolic dysfunction – left, right or bi-ventricular dysfunction	Echocardiographic evidence of dysfunction
Cardiogenic shock lasting more than 1 h	Low systolic blood pressure <90 mm Hg and/or Low cardiac output – <2 L/min/m^2 Despite adequate intra-cardiac filling pressures – CVP >15 mm Hg and/or PAoP >20 mm Hg
Circulatory support	Mild: Low dose inotropes Moderate: High-dose inotropes (Inotrope score >10) or need for IABP Severe: Need for total circulatory support: extracorporeal membrane oxygenation (ECMO) or equivalent
Exclusion of secondary causes of primary graft failure (PGF)	For example cardiac tamponade and hyperacute rejection

CVP , Central venous pressure; *IABP* , intra-aortic balloon pump; *PAoP* , pulmonary artery occlusion pressure.

Table 117.5

Recognised risk factors for primary graft failure after heart transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age >30 years	Age >60 years	Ischaemic time >180 min
Cardiac dysfunction on echo	Ventilator support	Donor-recipient weight mismatching
High-dose inotropic support	Intravenous inotropic support, mechanical support	Female donor to male recipient
Cause of brain death	Pulmonary hypertension	Concomitant lung retrieval
Primary graft dysfunction of other organs	Overweight, diabetes mellitus	

The management of PGF depends on the severity and the mechanism. RV failure is commonly the main contributor. The donor heart, especially when it is young and comparably small, cannot easily adapt to the often-observed pulmonary hypertension and increased PVR of the recipient. Additionally, adaptation of the donor heart may be impaired by IRI associated with organ preservation and inflammation triggered by CPB. As a result, the RV dilates and becomes ischaemic which further reduces contractility. The decrease in pulmonary blood flow and the leftward shift of the interventricular septum leads to a change of the LV shape, a lower LV preload and a reduction of systemic pressure and cardiac output, which further impairs coronary perfusion. Principles of management of RV failure are listed in Table 117.6 .

Table 117.6

CVP , Central venous pressure; *PVR* , pulmonary vascular resistance; *RV* , right ventricle.

Small reports suggest that levosimendan may be a useful, adjunctive inotropic drug in the treatment of patients with primary graft dysfunction after heart transplantation. [39], [40] In severe cases, implantation of an acute right ventricular assist device (RVAD) may be required. Longer-acting agents, such as oral sildenafil, may be required to allow weaning of nitric oxide and RVAD support in such cases. In severe cases of left- or bi-ventricular failure, the early institution of MCS is essential to avoid multiorgan failure. The most widely used MCS device is VA-ECMO, which can be deployed by either peripheral or central cannulation. Support may be required for 7 days or longer. [41-43]

Infections

Infections encountered in heart transplant recipients during the ICU phase of management are similar to those affecting other cardiac surgical cases. Risk factors for bacterial infection that are of particular importance include pre-transplant mechanical or ventilator support and the need for high-dose peri-operative immunosuppression. Other factors associated with an increased risk in the ICU patient, such as previous colonisation with multi-resistant bacteria, large volume blood loss and transfusion, AKI and invasive lines, also apply to the heart transplant recipient. Classic signs of sepsis, such as high fever, may be masked or blunted by immunosuppressive therapy, so a high index of suspicion is required. Infections usually respond to conventional antibiotic therapy, but choice will depend on local sensitivities. The herpes simplex virus is common in the early post-transplant period and usually responds to oral acyclovir. Clinical infections with other viruses (e.g. herpes zoster and CMV) usually have a more delayed onset after the ICU phase of treatment. Oropharyngeal candidiasis is probably the most common fungal infection and is usually preventable with oral nystatin. Occasionally, patients may present with early candidaemia, which is an important consideration in the acutely septic patient. Other fungal infections, such as aspergillus, may also occur during the immediate post-operative period but more typically occur at a later time point. [26]

Acute Rejection

Acute rejection is an adaptive immune response mounted by the recipient against the transplanted donor organ. Classical acute rejection is predominantly a T lymphocyte-mediated inflammatory response directed against the grafted organ. As the rejection response progresses, graft injury in the form of myocyte necrosis and myocardial oedema develops. In more severe rejection, other inflammatory cells, such as eosinophils and neutrophils, are recruited into the myocardium, and myocardial haemorrhage may occur. Acute cellular rejection can occur at any time but is unusual during the first week. It may be suspected on clinical grounds but is often completely asymptomatic. Symptoms are often non-specific and include fatigue, dyspnoea and fever.

Diagnosis is based on the pathological finding of a lymphocytic inflammatory infiltrate on endomyocardial biopsy, and the grading of severity is based on the extent of the inflammatory infiltrate and the presence or absence of myocyte necrosis. [44] Most transplant programmes perform regular surveillance endomyocardial biopsies commencing at about 1-week post-transplant. Biopsies are repeated weekly for the first month post-transplant, fortnightly between months 1 and 3, monthly between months 4 and 6 then less commonly thereafter or may be performed at any time between scheduled biopsies if there is a clinical suspicion of rejection. Cardiac MRI is being considered in recent times as a feasible alternative to biopsy for rejection surveillance. [45]

The overall rate of biopsy-proven acute rejection has been declining in recent years probably as a result of more effective immunosuppressive therapy. Historically, most patients experienced one or more episodes of acute rejection requiring ‘pulsed’ steroid therapy (e.g. intravenous methylprednisolone 0.5–1.0 g daily for three doses) during the first 3 months after transplantation; however, registry reports indicate that only one in three heart transplant recipients will require this during the first 12 months.[46]

Antibody-mediated rejection is also now recognised as a major cause of graft injury and loss. It occurs as a result of the formation of donor-specific antibodies in the recipient that are directed usually against donor human leukocyte antigens. These may be present pre-transplant as a result of previous transfusions, organ transplants, viral infections or pregnancies.[47] Hyperacute rejection occurring during the first hours or days post-transplant is usually triggered by the presence of preformed donor-specific antibodies in high circulating titres. Fortunately, this is now a rare event as donor-specific antibodies are normally detected by prospective or virtual cross-matching between the donor and recipient. Hyperacute rejection often presents with rapid onset of severe graft dysfunction and may be difficult to distinguish from PGF. Apart from acute circulatory support, treatment involves high-dose intravenous steroids, plasmapheresis and intravenous immunoglobulin. In more severe cases, monoclonal antibody treatments have been used, including rituximab and eculizumab.[29], [48]

Tricuspid Regurgitation

This is the most common valvular abnormality, occurring in 19%–84% of patients, depending on the definition of significant regurgitation. In the early stages after transplantation, most tricuspid regurgitation (TR) is functional and is usually secondary to geometric distortion of the AV annular ring, and preservation of atrial and tricuspid annulus geometry may prevent the development of TR. The ISHLT guidelines recommend that patients who are identified after surgery as having moderate-to-severe TR should have a repeat echocardiogram in the first 24 hours after the transplantation. Most patients can be managed conservatively, mainly with diuretics, and only rarely do they require surgical intervention. Routine endomyocardial biopsies, which are required for monitoring rejection, may contribute to the TR.[49-51]

Late Complications

Late complications of cardiac transplant, which are sometimes encountered in the ICU patient include:

Cardiac allograft vasculopathy – this is among the primary causes of death after the first year. This disease, which is atherosclerotic in nature and progresses rapidly, is characterised by persistent perivascular inflammation and intimal proliferation. It is sometimes considered to be a manifestation of chronic rejection. Early diagnosis is limited due to the scarcity of clinical symptoms of ischaemia in the denervated graft.[52, 53]

Neoplasms are among the major causes of late mortality with a two- to fourfold increase in risk compared to the general population. This elevated risk is related to the immunosuppression regimen and includes the malignant tumours related to viral infections, such as lymphoma (as a part of the PTLD) – both linked to infection by the Epstein–Barr virus, Kaposi sarcoma (related to the human herpesvirus 8), anogenital cancers (linked to the human papilloma virus) and hepatic cancer (hepatitis B and C virus).[54, 55]

Lung transplantation

Priya Nair, Stephen Morgan, Paul Jansz and Marshall Plit

Introduction

Lung transplantation commenced in the 1960s but, as with heart transplantation, early results were poor, and the procedure was largely abandoned until the 1980s. During the next decade, single and bilateral lung transplantation emerged as viable procedures for patients with end-stage lung disease. The International Society for Heart and Lung Transplantation (ISHLT) registry reports more than 55,000 lung transplants and currently, internationally, more than 4000 lung transplants are performed each year. [1] Post-transplant survival, although not as good as for other organs, has improved steadily. In the most recent ISHLT report, median post-transplant survival was 7 years with 80% survival at 1 year, 54% at 5 years and 32% at 10 years.

Historically, the vast majority of donors had undergone brain death-donation after brainstem death (DBD). More recently, donation after circulatory determination of death (DCDD) has re-emerged as an important source of donor lungs and in some programmes up to one-third of lung transplants are performed from DCDD donors. [2]

Virtually all of the improvements in survival have been during the first few months after transplantation. This can be explained by advances in immunosuppressive therapy, with fewer deaths due to uncontrolled rejection or infection, and better patient selection. Nonetheless, the first few days and weeks after transplantation are still a period of high mortality risk due mainly to the complications of primary graft dysfunction (PGD) or overwhelming infection.

Selection of Patients for Lung Transplantation

The primary indication is the presence of advanced, non-malignant lung disease for which there is no alternative therapy. Guidelines for selection have been extensively reviewed elsewhere. [3] The major disease categories are chronic obstructive pulmonary disease (COPD)/emphysema including alpha$_1$-antitrypsin (AAT) deficiency, pulmonary fibrosis, cystic fibrosis (CF), bronchiectasis and pulmonary vascular disease. Collectively, these diseases account for over 90% of cases. Bilateral lung transplantation is the most commonly performed, and accounts for approximately 75% of procedures. [3] Single lung transplantation is still performed for pulmonary fibrosis, particularly in older patients to reduce intra-operative risk. Combined heart/lung transplantation is now a relatively rare procedure due to relatively less favourable outcomes.

A critical aspect of the decision-making regarding suitability is the capacity of the patient to survive the stresses of surgery and post-operative recovery. For this reason, patients who are either acutely or significantly comorbid are deemed unsuitable. Objective criteria for defining these characteristics are lacking and decisions have, to a large extent, been based on clinical judgement. Quantitative measures of frailty may provide a more objective measure on which to base decisions; however, considerable further research is required. [4] The problem has been further compounded by the lack of an ‘artificial lung’ to bridge patients on ventilatory support and enable participation in a prehabilitation programme prior to transplant surgery. Extracorporeal membrane oxygenation (ECMO) support in ambulatory patients or the use of extracorporeal carbon dioxide removal devices may go some way towards addressing this limitation. [5]

In general, patients with acute respiratory failure (e.g. acute respiratory distress syndrome [ARDS] and pneumonia) requiring ECMO are not considered suitable due to the uncertain recovery from the underlying illness. Proposed contraindications for transplantation in this patient group are listed in Table 118.1 . Due to the lack of evidence, these are based on small case series and expert opinion.

Table 118.1

Proposed contraindications for bridging to transplant from extracorporeal membrane oxygenation

Irreversible extra pulmonary organ failure
Septic shock
Severe arterial occlusive disease
Relative
Advanced age
Limited institutional experience
Poor pre-morbid functional status with limited rehabilitation potential
Obesity (BMI >30)
Heparin-induced thrombocytopaenia
Prolonged mechanical ventilation

BMI , Body mass index.

The Potential Lung Donor

The donor’s lung has a greater tolerability to the sequelae of brain death and subsequent insults associated with lung retrieval and transplantation than was initially considered. In particular, the tolerability of ischaemia-reperfusion injury (IRI) is better than that of the heart. Donor lung function appears to be less affected by age and donors up to age 75 years are considered. DCDD donors account for increasing proportions of solid-organ transplants.

Donor Eligibility Criteria

These vary between jurisdictions and categories for standard and higher-risk donors (see Table 118.2). Whilst there have been concerns that the use of higher-risk donors will lead to increased rates of PGD and death, for characteristics such as donor age, donor or mode of death (DCDD vs DBD) this has not been corroborated. [6] Moreover, the risk associated with donors with characteristics associated with higher mortality (e.g. smoking) needs to be balanced against the risk of death on the waiting list. [7] Intensive care management of the donor is covered in another chapter 115 .

Table 118.2

Standard versus higher-risk criteria for donor lungs

DONOR PARAMETER	STANDARD CRITERIA	HIGHER-RISK CRITERIA (MARGINAL)
Age	<60 years	>60 years
Smoking history	<20 pack years	>20 pack years
Chest trauma	Absent	Present
Aspiration	Absent	Present
Chest X-ray	Clear	Abnormal
Arterial blood gases	paO_2 >300 mm Hg on FiO_2 of 1 (40 kPa)	paO_2 <300 mm Hg on FiO_2 of 1 (40 kPa)
Sputum	Nil or minimal	Purulent, documented infection
Bronchoscopy	Clear or minimal secretions	Purulent

Donor Lung Preservation

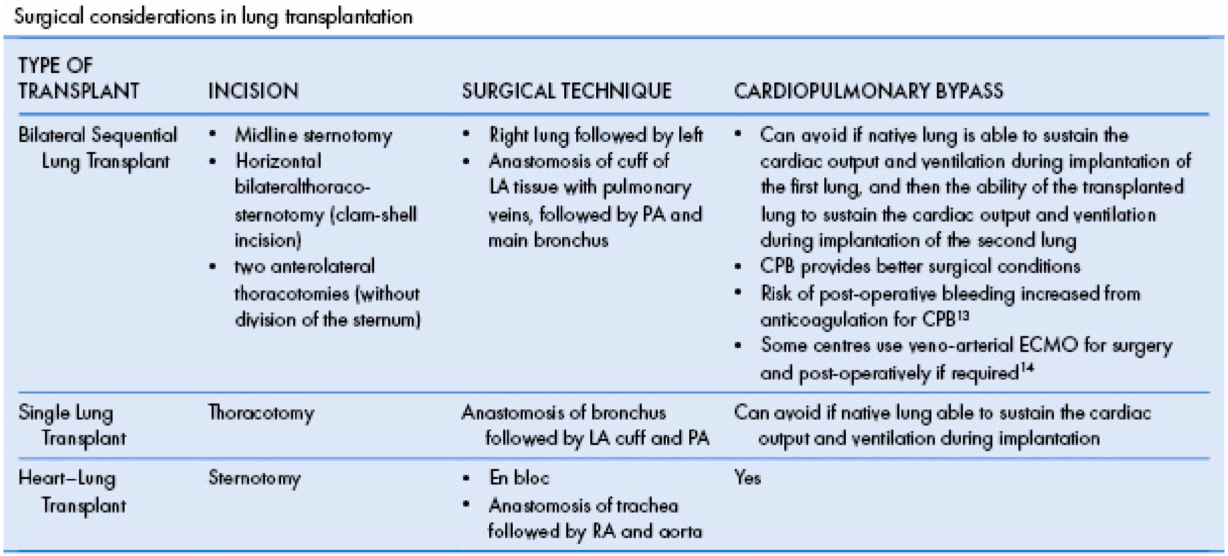
The major method of preservation has been the administration of a cold pneumoplegic solution followed by static storage in a preservation solution. Perfadex, a normokalaemic colloid (dextran 40) solution, has emerged as the favoured solution for both DBD and DCDD organs.

A major advance has been the use of ex-vivo lung preservation (EVLP) devices. This concept was first advanced by Steen[8,9] and later developed by Keshavjee,[10] who reported that EVLP could be used not only to prevent deterioration but also to restore function in lungs from extended criteria donors. Cold static preservation on ice (−4°C) has been the clinical standard of donor organ preservation. However, mitochondrial injury develops during prolonged donor lung storage which limits the time that organs can maintain viability.[11] Preservation at 10°C may however enable the preservation limit of about 6–8 hours to be prolonged.[12]

Lung Transplant Surgery

Bilateral lung transplantation was initially developed as an en-bloc technique with a single tracheal anastomosis; however, the high incidence of ischaemic anastomotic complications has led to this procedure largely being replaced by bilateral sequential single lung transplant (BSSLT) procedure. Surgical considerations are summarised in Table 118.3 .

Table 118.3



Surgical considerations in lung transplantation

TYPE OF TRANSPLANT	INCISION	SURGICAL TECHNIQUE	CARDIOPULMONARY BYPASS
Bilateral Sequential Lung Transplant	• Midline sternotomy • Horizontal bilateralthoraco-sternotomy (clam-shell incision) • two anterolateral thoracotomies (without division of the sternum)	• Right lung followed by left • Anastomosis of cuff of LA tissue with pulmonary veins, followed by PA and main bronchus	• Can avoid if native lung is able to sustain the cardiac output and ventilation during implantation of the first lung, and then the ability of the transplanted lung to sustain the cardiac output and ventilation during implantation of the second lung • CPB provides better surgical conditions • Risk of post-operative bleeding increased from anticoagulation for CPB[13] • Some centres use veno-arterial ECMO for surgery and post-operatively if required[14]
Single Lung Transplant	Thoracotomy	Anastomosis of bronchus followed by LA cuff and PA	Can avoid if native lung able to sustain the cardiac output and ventilation during implantation
Heart–Lung Transplant	Sternotomy	• En bloc • Anastomosis of trachea followed by RA and aorta	Yes

Anaesthetic Considerations

Specific recipient pathology and cardiorespiratory status should be taken into consideration. When surgery is performed off CPB, single lung ventilation needs to be safely and effectively established.

In addition to standard monitoring lines listed below, intra-operative transoesophageal echocardiography is used to evaluate volume status, assess myocardial (particularly right ventricular) function, assess pulmonary pressures, rule out intracardiac shunts and evaluate vascular (particularly pulmonary venous) anastomosis after allograft implantation. [15]

Post-Operative Management in the Intensive Care Unit

Physiology of the transplanted lung

Donor lung retrieval results in the interruption of the vagus and sympathetic nerves, pulmonary and bronchial blood vessels, and lymphatics. Whilst the pulmonary artery and pulmonary veins are anastomosed to those of the recipient, the bronchial arteries that supply the airways are not. The recipient's phrenic, vagus, and recurrent laryngeal nerves may be injured during the operative procedure, more commonly during heart–lung transplantation or when cardiopulmonary bypass is needed.

Respiratory Management

A key target of post-operative respiratory care is safe, early extubation to reduce the risk of ventilator-associated complications such as ventilator-induced lung injury, persistent air leaks and early infection. Patients are admitted ventilated via a single-lumen endotracheal tube with bilateral apical and basal intercostal catheters. [16] Thoracic epidural is considered the analgesic gold standard and is associated with shorter post-operative ventilation duration and reduced opioid requirement. [17, 18] Early bronchoscopy may be performed for diagnostic sampling and inspection of the bronchial anastomoses.

There are no high-quality data to support the use of a specific ventilator strategy in this patient population and current recommendations are extrapolated from the ARDS literature. [19] The application of protocolised ventilation based on ARDS guidelines is feasible [20] and include tidal volume of 4–8 mL/kg predicted body weight and plateau pressure <30 cmH$_2$O as standards of care. There are retrospective studies that have reported associations between a higher intensity of ventilation and early respiratory mechanics with short-term patient outcomes. [20-23] The FiO$_2$ should be minimised to target a PaO$_2$ of 60–80 mm Hg as hyperoxia may exacerbate the severity of IRI and normocarbia is essential to minimise pulmonary vascular resistance.

There are multiple factors that differentiate lung transplant recipients from a conventional ARDS patient population and may affect the safety of mechanical ventilation. These include surgical access, exposure to CPB or ECMO, ischaemia-reperfusion, lung denervation, phrenic nerve dysfunction, patient-recipient size match, pleural complications and catheters, established right ventricular dysfunction and pre-operative frailty.

The ventilator management of single lung transplant recipients must reflect the differential respiratory mechanics of the native lung and allograft. In single lung transplantation with fibrotic disease, tidal volumes of 4 to 6 mL/kg donor-predicted body weight should be used to reduce the risk of overdistension of the more compliant allograft. In single lung transplantation with obstructive disease, maximising the expiratory time reduces the risk of dynamic hyperinflation of the native lung. [24] This dynamic hyperinflation may compromise allograft ventilation and hence gas exchange, which may indicate the need for double-lumen endotracheal tube placement and independent ventilation of the lungs.

International survey data suggests that tidal volume is more commonly selected with reference to recipient-predicted body weight. [25] Retrospective studies have reported that patients with undersized allografts are ventilated with unrecognised higher tidal volumes when indexed to donor-predicted body weight [26-28] and early lung protective ventilation based on donor anthropometrics was associated with reduced risk of severe PGD at 48–72 hours and increased 1-year survival. [23] This approach has not been assessed prospectively.

Despite the majority of patients being extubated in the first 24–36 hours, [25] persistent respiratory failure may indicate caution in the early transition to spontaneous modes of ventilation with the attendant difficulties in maintaining lung protective targets in patients with high respiratory drive. PGD is the most common cause of the requirement for prolonged mechanical ventilation (PMV), and early identification of treatable differentials such as hyperacute rejection and infection is essential. Adjunctive strategies for refractory hypoxaemia have not been formally assessed in this patient population. Survey data suggest that higher PEEP (>14 cmH_2O) is very rarely applied reflecting a potential association of higher airway pressures and reduced bronchial anastomotic perfusion. [29-31] Prone ventilation has been described but is not a standard of care due to lack of evidence and perceived risk related to thoracotomy wounds and intercostal catheters. [32] Preservation of the pulmonary vascular function indicates a role for inhaled pulmonary vasodilators both to ameliorate hypoxaemia and reduce right ventricular afterload.

ECMO can be used to support lung transplant recipients in all phases of their perioperative care with a recent trend of increased survival in retrospective studies.[33-35] In the post-operative period, VV-ECMO may be used as a continuation of intra-operative ECLS or initiated de novo in the most severe forms of PGD to normalise gas exchange, improve pulmonary haemodynamics and facilitate ultraprotective ventilation to support allograft recovery. Transplant recipients with pulmonary arterial hypertension may receive prophylactic post-operative VA-ECMO, which supports controlled reperfusion of the allograft in the context of left ventricular remodelling, severe diastolic dysfunction and hence increased incidence of severe PGD.[34,36] Registry data suggest post-operative ECMO is used in 5.1% of cases with prolonged ischaemic time and pre-operative ECMO support being associated with increased use of ECMO in the first 72 hours.[35]

A trial of non-invasive ventilation (NIV) or high-flow nasal oxygen may be instituted for post-extubation respiratory failure, though prolonged periods of high tidal volume NIV to prevent reintubation should be avoided. Following extubation failure, investigations including diaphragmatic ultrasound and fluoroscopy may identify phrenic nerve palsy and early tracheostomy may facilitate weaning.[37] PMV is reported at rates of 14%–28% depending on the definition used and is consistently associated with reduced survival.[38,39] However, a single-centre study demonstrated hospital survivors had similar outcomes compared to patients who did not require PMV.[38] Increased risk of PMV has been associated with severe PGD, recipient BMI, renal replacement therapy, re-exploration for bleeding, anastomotic dehiscence, and neurological complications.[38-40]

Haemodynamic Management

The assessment of the heart–lung interactions is a fundamental and challenging aspect of the lung transplantation post-operative phase.

Pulmonary artery catheters are a useful monitoring adjunct in this phase and are used in most larger transplant centres. The initial goal is to maintain adequate end-organ perfusion, which is monitored by measuring lactate, urine output, and mixed venous oxygen saturation, with the lowest possible cardiac output (cardiac index of 2.2–2.5 $L/min/m^2$) to reduce the risk of exacerbating reperfusion injury.[41]

The post-operative period of the lung transplantation patient can also be complicated by other cardiac events, such as pericarditis, supraventricular tachyarrhythmias, myocardial ischaemia and pulmonary venous anastomotic–related dysfunction or torsion, inducing pulmonary oedema.[41] In particular, atrial fibrillation is reported with a variable incidence between 20% and 39%. The most common risk factors for post-operative atrial fibrillation in lung transplantation include electrolyte imbalance, gas exchange abnormalities, pain, fluid overload, vasopressors and inotropes, airway issues, and pericardial effusion. The management included ensuring adequate levels of plasma electrolytes (K^+, Mg^{++}) are maintained whilst applying a rate control strategy with antiarrhythmic drugs as a first-line approach in haemodynamically stable patients. Electrical cardioversion is reserved for unstable patients or those refractory to medical therapy.[42]

Calcineurin inhibitors (CNIs) in combination with corticosteroids predispose these patients to arterial hypertension. This should be treated assiduously to reduce the risk of acute neurological complications.

Fluid Balance and Renal System

The overall estimated incidence rates of acute kidney injury (AKI) and severe AKI requiring renal replacement therapy (RRT) in patients after lung transplantation are 52.5% and 9.3%, respectively. Despite advances in therapy, the incidence of AKI in patients after lung transplantation does not seem to have decreased. In addition, AKI after lung transplantation is significantly associated with reduced short-term and long-term survival.[43]

A restrictive fluid strategy is recommended to minimise the risk of pulmonary oedema. Pilcher et al. demonstrated an increased duration of ventilation, intensive care unit (ICU) and hospital mortality in lung transplant recipients who had a central venous pressure (CVP) greater than 7 mm Hg after excluding the effect of poor myocardial function and high inotrope requirement.[44]

Diuretics should be considered to mobilise fluid retention seen in the post-operative phase, and a further consideration is the absence of lymph drainage from the transplanted lung. On the other hand, hypovolaemia in combination with CNIs may predispose to pre-renal AKI.

In case of AKI, early RRT with fluid removal to minimise allograft oedema may be required. Both CNIs and diuretics increase urinary magnesium excretion and hence regular checks and supplementation are required to prevent arrhythmias and lower seizure threshold. [45]

Blood Management

As with other critically ill patients, the use of blood and blood products should be rationalised. Transfusion of red cells has been shown to be an independent factor for worse outcomes in lung transplant recipients. [46] Another study showed no effect on all-cause mortality with red cells, but higher adjusted 1-year mortality associated with platelet transfusion. [47] Point-of-care testing with viscoelastic tests (thromboelastography and thromboelastometry) and a goal-directed transfusion algorithm are used in some centres to rationalise blood management. However, transfusion-related immunomodulation (TRIM) might ameliorate rejection risk, although sensitisation with foreign antibodies may increase it. [15]

Gastrointestinal System and Nutrition

Vagal disruption and gastroparesis make reflux common and therefore proton pump inhibitors are administered routinely. In addition, prokinetic agents, such as domperidone, are used and reverse Trendelenburg position is maintained.

Patients who are not extubated early should have a nasogastric tube inserted and enteral nutrition with high protein content (along with pancreatic enzymes in the CF population) is desirable. [45] A combination of stool softeners and stimulants (e.g. coloxyl with senna) and osmotic laxatives are used. Further measures such as Gastrograffin (Diatrizoate Meglumine) may be required if the return of bowel function is delayed. Intravenous immunosuppressive drugs are switched to the enteral route only when gastrointestinal function has recovered, and efficient absorption is anticipated.

Immunosuppression

Induction therapy, with a move away from polyclonal antithymocyte preparations to interleukin (IL)-2 receptor antagonists or alemtuzumab is increasingly used. ISHLT data suggest a small improvement in survival in patients receiving induction therapy. [48]

Maintenance immunosuppression involves the administration of three drugs in combination: corticosteroids, an antimetabolite (mycophenolate mofetil [MMF] or azathioprine) and a calcineurin inhibitor (CNI-cyclosporine or tacrolimus). Tacrolimus and MMF are the preferred CNI and antimetabolite, respectively. Recipients with CF are administered their cyclosporine with a pancreatic enzyme supplement.

Highly sensitised lung transplant recipients should be identified before transplantation. Various high-risk scenarios include:

1. Waitlist recipients with match calculated panel reactive antibodies (cPRA) >40% should be discussed before transplantation.
2. Pre-transplant donor-specific antibodies (DSA) and a positive T or B cell X-match (in the presence of DTT), should be desensitised as per the Toronto protocol for the transplant to proceed safely.
3. Single or multiple moderate to strong mean fluorescence intensity (MFI) >6000) pre-transplant DSAs with a negative T/B cross-match should be considered for desensitisation.
4. Weak to moderate (MFI <6000) pre-transplant DSA and negative X-match may be safe to transplant with the administration of post-operative intravenous immunoglobulin (2 g/kg over 3 days). These patients should be monitored closely for a strong memory B cell response causing delayed primary graft dysfunction. [49]

Infection Prophylaxis

Lung transplant recipients are at high risk of infection, more so than other transplant recipients, as the transplanted lung uniquely is in direct contact with the external environment and any potential airborne pathogens. Often the donor has evidence of lower airway colonisation or infection prior to retrieval. In the recipient, there is impaired ciliary function and loss of the cough reflex resulting in retained secretions. In addition, a substantial proportion of recipients, those with CF or bronchiectasis, are invariably colonised with multi-resistant bacteria in the upper respiratory tract at the time of transplantation. These organisms can rapidly spread to the lower respiratory tract.

Bacterial prophylaxis: Donor sputum or bronchoscopy samples are used to guide therapy. For recipients with chronic suppurative lung disease, antibiotic prophylaxis will depend on sensitivities determined from pre-transplant surveillance. Targeted antimicrobial therapy to known donor organisms appears effective in modulating infection after transplantation. Otherwise, a third-generation cephalosporin with broad spectrum against Gram-positive and negative organisms (e.g. cefotaxime) is administered.

Fungal prophylaxis : Pneumocystis jiroveci prophylaxis in the form of oral co-trimoxazole is commenced in the first-week post-transplantation and continued indefinitely. For patients who are allergic, dapsone or monthly inhaled pentamidine are suitable alternatives. Nystatin oral solution to prevent oropharyngeal candidiasis is also administered for the first few weeks post-transplant. Aspergillus infections are less common but potentially catastrophic. Inhaled amphotericin has been shown to significantly reduce the incidence of *Aspergillus* and other fungal infections and is administered routinely until hospital discharge. An alternative approach to *Aspergillus* prophylaxis is the use of oral azoles such as voriconazole or posaconazole. [50]

Viral prophylaxis: Cytomegalovirus (CMV) may cause life-threatening pneumonitis and has been associated with an increased risk of the development of bronchiolitis obliterans syndrome (BOS). Risk is highest in recipients of lungs from CMV-seropositive donors, particularly when the recipient is CMV-negative (D+/R−). Although clinical infection is extremely uncommon in the first month post-transplant, it is essential to commence prophylaxis immediately. Intravenous ganciclovir is administered initially, followed by oral valganciclovir (dose adjusted for renal function). The 2013 American Society of Transplantation guidelines recommend 12 months of prophylaxis for D+/R− lung transplant recipients. Valganciclovir is administered for 6 months in D+/R+ and D−/R+

recipients. CMV hyperimmune globulin is also administered for up to 1 month to D+/R− recipients.[51]

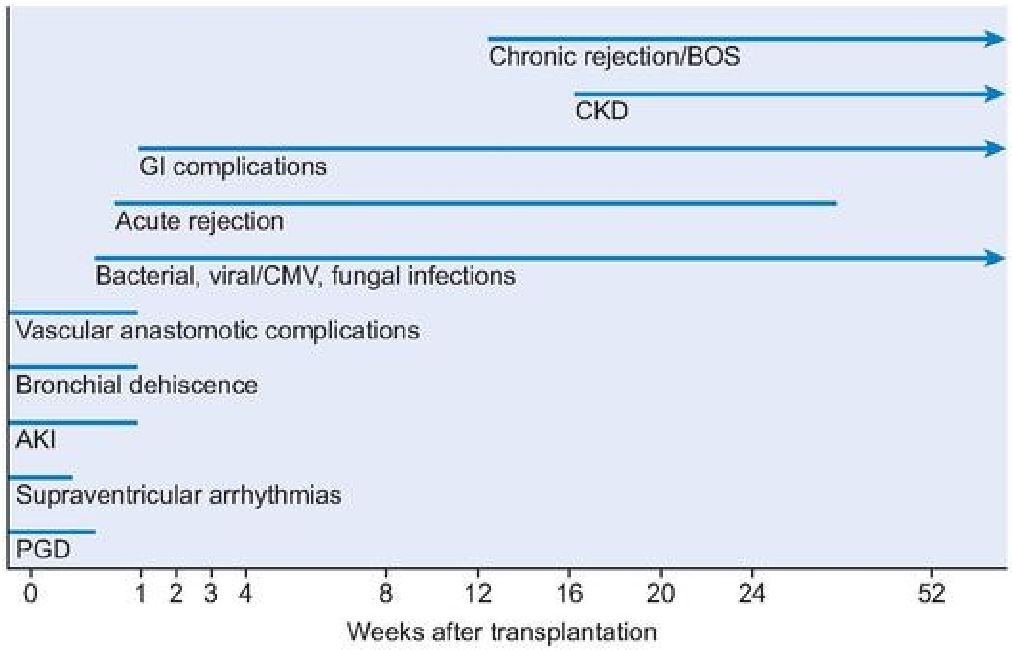
Recipients who are Epstein–Barr Virus (EBV) naïve who receive lungs from EBV-seropositive donors (D+/R−) are at high risk of developing post-transplant lymphoproliferative disorder (PTLD), which carries a very high mortality. If they are not already receiving oral valganciclovir, EBV D+/R− recipients are maintained on valaciclovir indefinitely.

Miscellaneous drugs

Other drugs administered in the immediate post-transplant period include an insulin infusion as required to control hyperglycaemia, which is common following the administration of high-dose steroids, calcium and vitamin D supplements to prevent osteoporosis and subcutaneous unfractionated heparin for deep vein thrombosis (DVT) prophylaxis.

Complications

In addition to immediate post-operative complications, lung transplant recipients may require ICU admission with respiratory or non-respiratory complications in the weeks or months following transplantation. Fig. 118.1 indicates the timeline of potential complications that may require intensive care management. Recipients may be readmitted into non-transplant hospital ICUs and a basic understanding of the special complications and requirements of these patients is therefore important. However, it is strongly recommended that early communication and close cooperation between transplant centres and regional ICUs is undertaken.



The horizontal timeline chart maps the onset and duration of complications following organ transplantation. The horizontal axis represents weeks after transplantation, ranging from 0 to 52. Each complication is listed on the vertical axis with a corresponding horizontal line indicating its typical period of occurrence. Primary graft dysfunction (P G D), supraventricular arrhythmias, acute kidney injury (A K I), bronchial dehiscence, and vascular anastomotic complications occur early, mostly within the first 4 weeks. Bacterial, viral, cytomegalovirus (C M V), and fungal infections begin early and can persist throughout the first year. Acute rejection typically arises between weeks 1 and 24. Gastrointestinal (G I) complications span nearly the entire year. Chronic rejection and bronchiolitis obliterans syndrome (B O S), along with chronic kidney disease (C K D), typically emerge later, around 20 weeks, and continue beyond 1 year. Rightward arrows indicate ongoing or persistent risk.

FIG. 118.1 Time course of complications following transplant. *AKI* , Acute kidney injury; *BOS* , bronchiolitis obliterans syndrome; *CKD* , chronic kidney disease; *CMV* , cytomegalovirus; *GI* , gastrointestinal; *PGD* , primary graft dysfunction.

Primary graft dysfunction (PGD)

This is a multifactorial clinical syndrome of acute lung injury unique to the first 72 hours after lung transplantation. [52] PGD is the most common early complication and is associated with increased early mortality, PMV and chronic lung allograft dysfunction (CLAD). [53] , [54] The PGD definition was revised in 2016 and it requires the presence of bilateral infiltrates on chest imaging with severity grading (0–3) based on the PaO_2 :FiO_2 (P:F) ratio [52] (Table 118.4). Approximately 25%–30% of patients develop PGD grade 3 within 72 hours, which is defined by a P:F ratio <200 mm Hg or requirement for VV-ECMO for hypoxaemia post-transplant. Despite exhibiting many similarities to ARDS, the updated definition does not include an additional severity grade with a P:F ratio <100 mm Hg due to a lack of supporting evidence. Epidemiological data have confirmed the predictive validity of the mutually exclusive severity grades with respect to patient outcomes and the association of severe PGD with elevated biomarkers of both epithelial and endothelial cell injury. [55-57] Latent class analysis has suggested that patients with persistent high-grade PGD at 48–72 hours represent a sub-phenotype with worse short- and long-term outcomes. [58]

Table 118.4

PGD , Primary graft dysfunction.

The pathophysiology of PGD is complex and understanding of the risk factors, mechanisms and potential therapeutic targets is continuously evolving.[59,60] Risk associations have been identified related to recipient, donor and procedural factors (see Table 118.5). Increased pulmonary vascular permeability and extravascular lung water are the final common pathways and are responsible for heterogeneous lung aeration, reduced compliance, increased shunt fraction and radiographic infiltrates. The inciting event is ischaemia-reperfusion during organ retrieval, storage and implantation. Reactive oxygen species generation and activation of innate immune system inflammatory cascades ultimately disrupt alveolar-capillary membrane integrity leading to interstitial and alveolar oedema.[61,62] For procedures performed without ECLS (either CPB or V-A ECMO), hyperperfusion of the lung that is implanted first and must accommodate the entire cardiac output may contribute to lung oedema and disruption of pulmonary lymphatics reduces the rate of oedema clearance in all recipients.

Table 118.5

Recognised risk factors for primary graft dysfunction after lung transplantation

DONOR FACTORS	RECIPIENT FACTORS	PROCEDURAL FACTORS
Age <21 years or >45 years	Female sex	Single lung transplantation
Smoking >20 pack years	Ventilator support	Cardiopulmonary bypass
Pneumonia on X-ray or purulent secretions on bronchoscopy	Pulmonary fibrosis	Prolonged ischaemic time
Primary graft dysfunction of other organs	Pulmonary hypertension Obesity Sarcoidosis	>1L Packed Red Cells

To date there are no specific treatments available for PGD and the focus is on optimising supportive care based on the principles of management of ARDS. [60] Currey et al. demonstrated that implementation of an evidence-based algorithm for respiratory and haemodynamic management in the post-operative period was feasible and was associated with a reduction in severity of PGD. [20] In the immediate post-operative period, coincident pathologies may masquerade as PGD and exacerbate the severity of hypoxaemia. The clinician should aim to identify and treat these potential confounders such as bronchial anastomotic stenosis or dehiscence, left ventricular diastolic or systolic dysfunction, pulmonary venous anastomotic obstruction, early rejection and pleural complications.

Infections

Pneumonia is the most common type of bacterial infection after transplantation, and *Pseudomonas aeruginosa* is the most common cause, followed by *Staphylococcus aureus* . Early pneumonia in the lung transplantation patient is more often related to the recipient ICU nosocomial flora than the donor ICU flora. Pneumonia is associated with several risk factors, including exposure of the graft to the external environment through the airway, aspiration, interruption of graft innervation potentially impairing adequate coughing and mucociliary clearance, post-operative interruption of lymphatic drainage and anastomotic complications. [63]

Invasive fungal infections in lung transplantation have been associated with high morbidity and mortality, and are most often caused by *Aspergillus* but can also include non- *Aspergillus* species like *Scedosporium* , mucormycosis and Zygomycetes. Reported risk factors include fungal colonisation, idiopathic pulmonary fibrosis, older age, increased body mass index, airway ischaemia, single lung transplantation, severity of recipient's clinical condition and major construction projects around the hospital. [64]

Angioinvasive aspergillosis infection – although rare – may result in rapidly progressive necrotising pneumonia, bronchial anastomotic dehiscence or even pulmonary arterial or venous anastomotic dehiscence, leading to exsanguinating haemoptysis. An aggressive diagnostic approach – including bronchial washings or computed tomography (CT)-guided fine needle aspiration of focal pneumonic lesions to look for respiratory viruses and CMV, bacteria, fungi and pneumocystis jiroveci pneumonia (PJP) – is essential to facilitate early diagnosis and the initiation of appropriate treatment.

Bloodstream infections are also severe complications in lung transplantation recipients (incidence approximately 25%) and are associated with graft failure and increased mortality (25% for bacteraemia, up to 50% for candidaemia). [63]

Empyema, surgical wound infection, mediastinitis and pericarditis are other infective complications occurring after lung transplantation with a considerable effect on mortality. [65]

Acute Rejection

The incidence of acute rejection after lung transplantation has been declining. The ISHLT Registry reports that 28% of patients undergo treatment for acute rejection during the first 12 months after transplantation.[48] Hyperacute rejection is a form of humoral rejection that occurs in the first 24 hours following transplantation in recipients who have pre-formed anti-human leucocyte antigen (HLA) antibodies. With improved sensitivity of testing, it is rarely seen, but it needs to be distinguished from IRI.

Symptoms and signs of acute rejection are non-specific and include dyspnoea, cough, sputum production, fever, declining FEV$_1$ (forced expiratory volume at 1 s) on spirometry and the appearance of alveolar infiltrates. The major differential diagnosis is lower respiratory tract infection. If unrecognised and untreated it can lead to rapid onset of severe graft dysfunction and a clinical picture of ARDS. It is important to remember that rejection and infection can occur simultaneously. Transbronchial biopsy and bronchial washing are required for pathological confirmation. The severity of acute lung rejection is graded histologically.[66] Treatment for biopsy-proven acute rejection in the first instance involves pulsed steroid therapy.

Respiratory failure occurring during the first 72 hours after transplantation is usually due to PGD. However, respiratory failure occurring at any time after this suggests another cause – usually either infection or rejection. Acute cellular rejection is very uncommon in the first-week post-transplant, but acute antibody-mediated rejection (AMR) may occur if there are pre-formed DSAs. Treatment of acute AMR is intensive and involves a combination of plasmapheresis, high-dose intravenous immunoglobulin (IVIG) and MabThera.

AMR can also occur later and is usually associated with acquired anti-HLA and less commonly non–anti-HLA antibodies. The relationship between the level of antibodies and loss of lung function does not have a high positive predictive value. Unlike AMR in other solid-organ transplant recipients, there are no standardised diagnostic criteria. Key diagnostic criteria include the presence of new or increasing antibodies directed towards donor HLA and characteristic lung histology showing evidence of capillary injury within the graft. Exclusion of other causes of allograft dysfunction increases confidence in the diagnosis.[67]

Airway Complications

Peri-anastomotic bronchial ischaemia is relatively common, as re-anastomosis of the bronchial arteries is not performed. The establishment of bronchial blood flow to the transplanted lung occurs over the first-month post-transplant via ingrowth of collaterals from the recipient, but until then the transplanted lung is reliant on low-pressure retrograde collateral bronchial flow of (deoxygenated) blood from the pulmonary artery. Major airway complications were reported in 1.4% of lung transplant recipients in a contemporary United Network for Organ Sharing (UNOS) Registry analysis. Although rare they are associated with significant morbidity and mortality. Ischaemia of the anastomosis predisposes to a number of airway complications including bronchial stenosis at or beyond the anastomosis, bronchomalacia, endobronchial infections and bronchial anastomotic dehiscence. The latter is often associated with persistent large air leaks and development of fatal mediastinitis. Repeated bronchoscopic assessment of the anastomosis is undertaken during the first 4 to 6 weeks until healing is complete. A variety of bronchoscopic interventional procedures have been developed to treat airway complications, including balloon angioplasty and stenting.[68, 69]

Chronic Lung Allograft Dysfunction

Chronic lung allograft dysfunction (CLAD) can present either as a predominantly obstructive ventilatory pattern – BOS, a restrictive pattern or a mixed pattern. It is staged from 0 to 4 and is diagnosed when the FEV1 declines irreversibly below 80% of the baseline on at least two occasions.[70] CLAD is defined by the exclusion of known conditions such as infection, acute rejection and main airway stenosis. It is assumed that the predominant cause of CLAD is chronic rejection. Treatments of CLAD include optimisation of immune suppression, including treatment for AMR when suspected. Other measures include the addition of Everolimus, Azithromycin and the consideration of Montelukast.

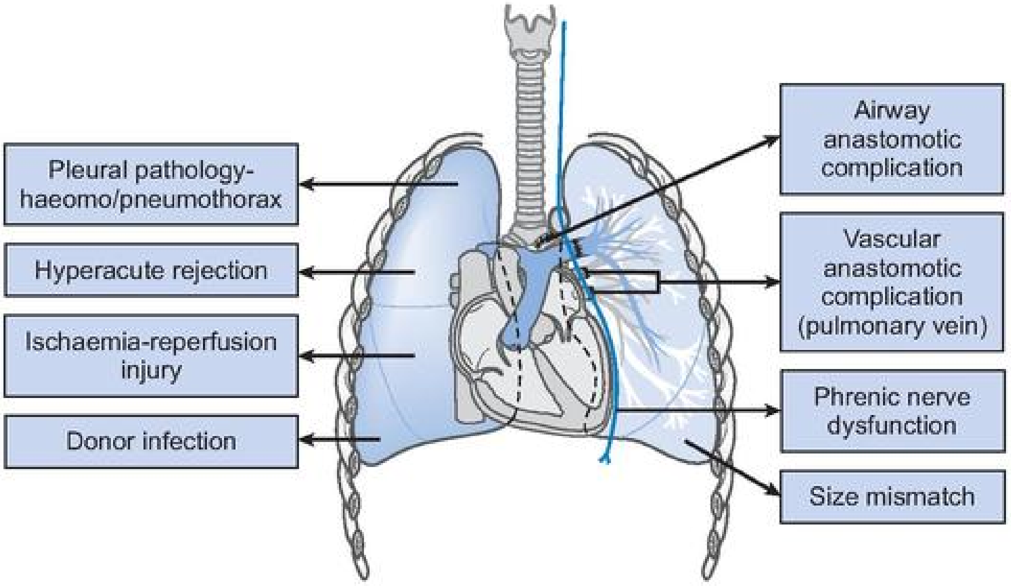
Patients may require admission into the ICU for complicating infection and ventilatory support. The incidence is highest after the first year; however, the risk increases to 60%–80% 5–10 years after transplantation, although meticulous targeting of cyclosporin levels has demonstrated reduced rates. It is the major complication that adversely affects long-term survival, and may be progressive, may plateau or may progress gradually. Treatment for established CLAD has not proven to be effective; consequently, in the event of progressive deterioration, PMV or ECMO is not recommended unless imminent re-transplantation is being considered in special circumstances. The severity of lymphocytic bronchiolitis on transbronchial biopsies is associated with an increased risk of BOS and death independent of acute rejection. The ISHLT recommendations are conditional, due to low-quality evidence, and include switching from cyclosporine to tacrolimus, a trial of azithromycin, consideration of anti-reflux surgery for patients with confirmed gastro-oesophageal reflux and re-transplantation for end-stage refractory CLAD. [71]

Other Pulmonary Complications

Complications associated with vascular anastomoses, size mismatch and phrenic nerve injury may also be encountered in the post-operative period (Table 118.6).

Table 118.6

Fig. 118.2 depicts the differential diagnosis of respiratory failure specific to the early post-transplant phase. Later in the course, in addition to the potential causes in any other patient, rejection (both cellular and antibody-mediated) and infection (particularly CMV, aspergillus, PJP) should be considered.



Pleural pathology-haeomo/pneumothorax
Hyperacute rejection
Ischaemia-reperfusion injury
Donor infection
Airway anastomotic complication
Vascular anastomotic complication (pulmonary vein)
Phrenic nerve dysfunction
Size mismatch

The labelled anatomical illustration shows the thoracic cavity, with both lungs, heart, trachea, and major bronchi depicted. Labels positioned around the view identify early complications after lung transplantation. On the left side, complications include pleural pathology such as hemothorax or pneumothorax, hyperacute rejection, ischemia-reperfusion injury, and donor infection. On the right side, complications listed are airway anastomotic complications, vascular anastomotic complications involving the pulmonary vein, phrenic nerve dysfunction, and size mismatch.

FIG. 118.2 Specific differential diagnoses for respiratory failure in the early post-transplant phase.

Extrapulmonary Complications

Complications affecting other organ systems may be affected at different times in the post-operative phase and need to be recognised promptly and managed appropriately (Table 118.7).

Table 118.7

CNI , Calcineurin inhibitors; *PRES* , posterior reversible encephalopathy syndrome.

Pharmacokinetics, pharmacodynamics and drug monitoring in acute illness

Christine Chung and Jason A. Roberts

Pharmacokinetics (PK) describes a drug's journey through the body, that is its absorption, distribution, metabolism and excretion over time. Pharmacodynamics (PD) is the physiological effect of a drug in the body. The relationship between the two can be used to predict how a drug will behave in a given patient leading to tailormade dosing regimens.

Manufacturer's dosing recommendations are often based on the PK-PD of a normal patient population. Whilst there may be guidance on dosing in special populations (e.g. liver and renal failure) there is rarely advice available on dosing in the critically ill with multiorgan failure or augmented renal clearance.

The complex, dynamic changes that affect PK and PD in the critically ill present significant challenges in treatment optimisation, especially with drugs that lack timely measurable parameters to determine dosing. As a patient improves or deteriorates clinically, drug regimens require adjustment to maximise benefit whilst minimising adverse toxic effects. The aim of this chapter is to provide the reader with the basic principles of PK and PD to aid in their understanding of drug dosing in critically ill patients.

Pharmacokinetics

Absorption

Bioavailability (*F*) is the fraction of administered dose that reaches the systemic circulation [1] and is dependent on many variables including absorption. For the intravenous (IV) route, *F* is usually 1 unless it is a prodrug, i.e. requires metabolism to its active form. For the oral route, *F* would also be less than 1 in the majority of cases as a percentage of drug is lost in its journey from the gastrointestinal tract to its site of metabolism, e.g. the bioavailability of digoxin liquid is 0.75. [2] Converting to an equivalent IV dose requires an approximate dose reduction of 25%.

Enteral

When a drug exists only in the oral form, the amount absorbed via the enteral route is governed by *general* factors such as:

- accessibility to site of absorption in the gastrointestinal tract [3]
- surface area available for absorption [3]
- delayed gastric emptying may increase the absorption of drugs absorbed in the acidic environment of the stomach; basic drugs usually absorbed in the small intestine may be reduced due to increased degradation in the stomach [4]
- gut transit time: increased, e.g. profuse diarrhoea may lead to reduced time for absorption and potentially therapeutic failure; reduced e.g. gastric outflow obstruction can cause enhanced effects by delaying transit [5]
- presence of enteral feed that may significantly reduce the efficacy of certain drugs, e.g. phenytoin is best administered in the middle of a 4-hour rest period from enteral feed [6]
- whilst their lipid content enhances the absorption of certain medicines, e.g. atovaquone
- presence of other drugs that may bind and reduce absorption if administered at the same time, e.g. ciprofloxacin and ferrous fumarate [7]
- formulation of drug administered, e.g. liquid often has increased bioavailability compared to tablet [8]

- extent of first-pass metabolism of the drug, if high can produce low oral bioavailability in a patient with a normally functioning liver and vice versa [1]

Factors affecting gastrointestinal absorption in the critically ill:

- compromised absorptive capacity by, e.g. hypoperfusion in septic shock [9] or gastrointestinal oedema
- reduced gut integrity [9]
- cholestasis which reduces absorption of lipid-soluble medicines due to lack of contact with bile salts [10]
- pH of stomach for modified release preparations to be released in correct site of the gastrointestinal tract can be affected by stress ulcer prophylaxis used in ICU, e.g. proton pump inhibitors [4]
- whether the pH of the stomach is optimal – the degree of ionisation affects lipophilicity and consequently the extent of absorption, e.g. proton pump inhibitors by raising stomach pH reduce the solubility of atazanavir, a weak basic drug which requires a low pH for absorption. [11]
- apical drug transporters (e.g. P-glycoprotein/multidrug resistance protein-1 that return drugs back to the intestinal lumen) limit bioavailability but are also affected by systemic inflammatory conditions, e.g. sepsis. [12]

Intramuscular and Subcutaneous

The effects of drugs given via intramuscular (IM) or subcutaneous (SC) routes can be unpredictable and dependent on local blood flow to tissues, adipose and muscle. Muscle perfusion is often significantly reduced in patients with haemorrhagic shock and/or in patients with high-dose vasopressor requirements making it an undesirable route of administration if rapid systemic effects are required. Oedema as a consequence of aggressive fluid resuscitation in sepsis can also reduce the bioavailability of e.g. SC enoxaparin, increasing the risk of a thromboembolic event if regular anti-Xa factor levels are not used to guide dosing.

Intravenous

The IV route is the most common form of drug administration in the intensive care unit (ICU) as it usually guarantees 100% bioavailability. However, it is still affected by:

- drug–drug incompatibility when drugs of very different pHs are administered via the same IV line (e.g. propofol [near neutral pH] and atracurium [acidic pH]) [13]
- drug–diluent incompatibility when a very acidic drug (e.g. amiodarone) is diluted with sodium chloride 0.9% (near neutral pH) [14] or a very basic drug (e.g. furosemide) is diluted with dextrose 5% (weakly acidic). [15]

Both of these scenarios can lead to precipitation of insoluble salts that may cause line occlusion, loss of drug efficacy and possible danger of systemic embolisation.

Other considerations for administration via the IV route:

- Temperature and light can lead to degradation of, for example parenteral nutrition [3] or sodium nitroprusside to cyanide ions, [16] requiring opaque covering of the infusion solution.
- Too much diluent can lead to some drugs precipitating out of solution, leading to loss of efficacy (e.g. amiodarone diluted beyond 0.6 mg/L). [13]

Distribution

Volume of distribution (V_d) is the theoretical volume of fluid into which the total drug administered would have to be diluted to produce the same concentration in plasma. It is unrelated to the volume of the body or its fluid compartments but rather to its distribution. [1]

Calculation of V_d :

$$V_d = \frac{A}{C}$$

A = total amount of drug in the body (mg), C = plasma concentration of drug (mg/L).

Therefore V_d is increased by factors in the following scenarios [1] :

- reduced protein binding (increased drug available for tissue binding)
- increased tissue binding
- increase in body fat (for fat-soluble drugs)
- oedema, ascites, effusion fluid and fluid resuscitation (for water-soluble drugs)
- in sepsis, endothelial damage and increased capillary permeability promote fluid leak from intravascular into interstitial spaces (for water-soluble drugs)
- positive-pressure mechanical ventilation, continuous renal replacement therapy (CRRT) or extracorporeal membrane oxygenation (ECMO) can increase V_d of hydrophilic drugs by promoting a more positive fluid balance or lead to drug sequestration of lipophilic or highly protein-bound drugs. [17]

Decreased V_d results from the opposite of the above.

For example gentamicin, a hydrophilic drug with minimal protein binding, has a low V_d similar to the extracellular fluid volume (0.25 L/kg). [18] In a septic, mechanically ventilated, fluid-resuscitated patient, the V_d of gentamicin increases as the effective extracellular volume increases, and a larger dose (A) is required to obtain therapeutic concentrations, e.g. 7–8 mg/kg/day as opposed to 5 mg/kg/day. [18, 19]

Lipophilic drugs distribute intracellularly and in adipose tissue and are not significantly influenced by fluid volume [17] but by other factors, e.g. phenytoin is 90% protein bound with a V_d similar to total body water

(0.65 L/kg).[1] Hypoalbuminaemia in critical illness increases the free, pharmacologically active fraction of phenytoin. This should be taken into account when interpreting phenytoin concentrations (normally reported as total serum concentrations that assume normal protein binding). The increased free fraction is available for metabolism and excretion.

Morphine extensively binds to tissue and has a high V_d 2–3 L/kg).[20] Uraemia displaces it from its tissue-binding sites, thereby increasing plasma concentration whilst reducing the V_d.

V_d is used to calculate the *loading dose (L_d)* ; that is the dose required to rapidly achieve a desired therapeutic concentration (C_p) of the drug:

$$L_d = \frac{V_d \times C_{pss}}{S \times F}$$

where C_{pss} = desired plasma concentration at steady state, S = salt factor of drug formulation (fraction of administered dose that is an active drug), F = bioavailability as a fraction.

Metabolism

Hepatic Drug Metabolism

The majority of drugs are metabolised via the liver. Hepatic drug clearance is affected by blood flow to the liver and the fraction of drug removed as it passes through, the extraction ratio (ER)[10] :

$$\mathrm{ER} = C_{in} - C_{out} / C_{in}$$

where C_{in} = concentration in; C_{out} = concentration out.

- *High-extraction drugs (>0.7)* have significant first-pass metabolism and low oral bioavailability. There is a relative excess of the enzymes that metabolise a drug (high intrinsic clearance) and a high proportion of the drug is removed by the liver before reaching the systemic circulation. The rate-limiting step is supply of the drug to the liver. Hepatic clearance depends on hepatic blood flow (proportional to cardiac output) and is unaffected by changes in the amount of active enzyme inhibition or induction and changes in free fraction. In septic shock, the hepatic blood flow is reduced due to hypoperfusion but in the hyperdynamic phase of sepsis, cardiac output is increased promoting perfusion of vital organs such as the liver. Conversely, in cirrhosis, functional hepatocytes are bypassed when intrinsic clearance falls or portosystemic shunts form, both of which increase drug bioavailability by diverting drug directly to the systemic circulation instead of the liver for metabolism.
- *Intermediate-extraction drugs PKs (0.3–0.7)* are more complex to predict. Drugs that fall into this category include those that are normally in the high ER group but alter in hepatic dysfunction with reduced metabolism causing accumulation of active drugs.
- *Low-extraction drugs (<0.3)* have negligible first-pass metabolism and high oral bioavailability. There is a relative deficit of enzymes that metabolise the drug (low intrinsic clearance) and the rate-limiting step is enzymatic activity. Hepatic clearance is independent of hepatic blood flow but is influenced by enzyme inhibition or enzyme induction, other competing drugs and changes in the free fraction of the drug (the form accessible to the enzyme). Reduced liver perfusion and a fall in ER do not significantly affect drug bioavailability.
- Hepatic dysfunction can reduce the effects of prodrugs that require metabolism to become active.

Table 119.1 shows high, intermediate and low hepatic ER drugs.

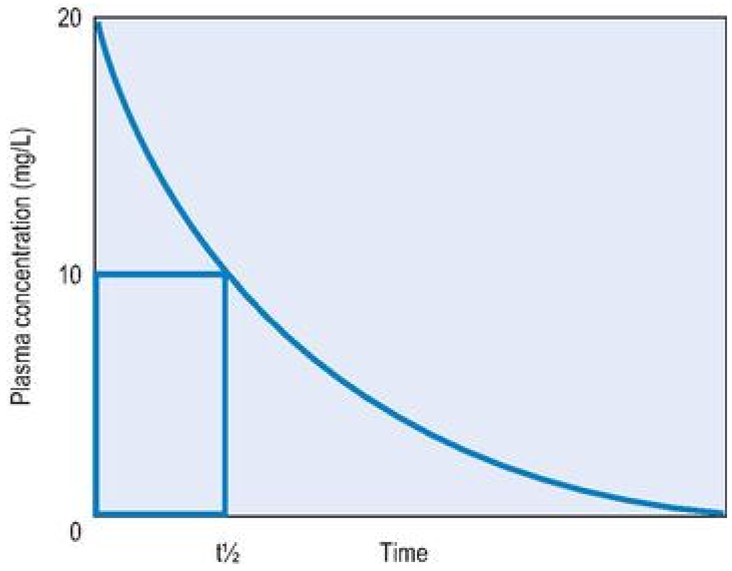
Table 119.1

High, intermediate and low-extraction ratio drugs [1]

HIGH ER> 0.7	INTERMEDIATE 0.3–0.7	LOW ER <0.3
Propranolol Morphine Fentanyl	Omeprazole Amiodarone Midazolam	Lorazepam Theophylline Phenytoin

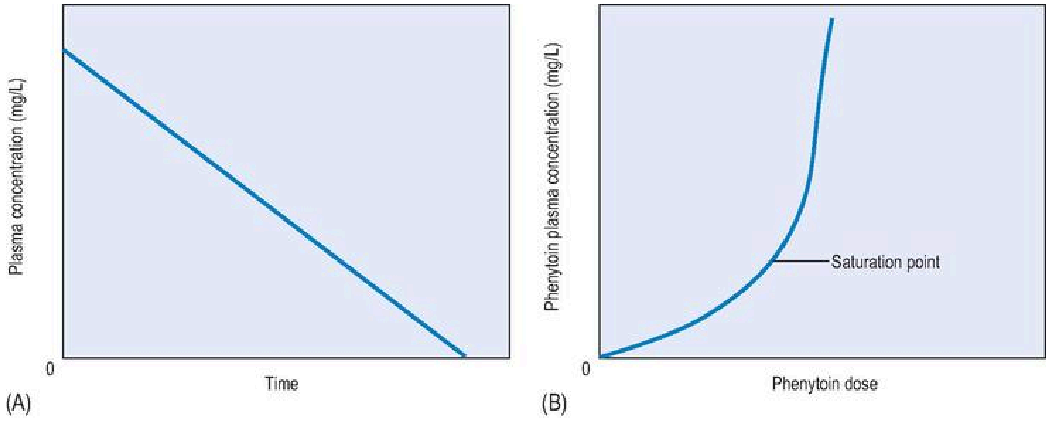
Zero-Order Metabolism

Most drugs follow first-order PK, i.e. rate of metabolism correlates proportionally with plasma concentration (Fig. 119.1). However, drugs such as phenytoin follow zero-order PK. Metabolism reaches its peak as the enzyme system is saturated and relative clearance falls as plasma concentrations rise. The process is concentration-independent, therefore an increase in dose will produce a disproportionate rise in plasma levels. The rate of metabolism is constant regardless of the amount of drug present (Fig. 119.2).



The graph plots plasma concentration in milligrams per litre on the vertical axis against time on the horizontal axis, exhibiting a typical exponential decay curve. The curve starts at 20 milligrams per litre and decreases over time. A horizontal line marks the concentration dropping to 10 milligrams per litre, and a vertical line from that point to the horizontal axis identifies the time corresponding to the drug half life, labelled as t one half.

FIG. 119.1 First-order elimination graph (plasma drug concentration vs. time).



The two graphs are labelled A and B. The graph in panel A depicts a linear decline in plasma concentration over time. The vertical axis is labelled plasma concentration in milligrams per litre, and the horizontal axis is labelled time. The graph shows a straight diagonal line descending from left to right, indicating consistent first-order elimination. The graph in panel B shows a nonlinear relationship between phenytoin dose and plasma concentration. The vertical axis is labelled phenytoin plasma concentration in milligrams per litre, and the horizontal axis is labelled phenytoin dose. The curve begins with a gradual rise and then increases steeply after reaching a labelled saturation point, indicating nonlinear pharmacokinetics.

FIG. 119.2 (A) Zero-order elimination. (B) Saturation point phenytoin pharmacokinetics.

Non-hepatic drug metabolism e.g. biliary, gut, lung and plasma esterases are affected by conditions that compromise accessibility or function e.g. cholestasis, gastrointestinal failure and pulmonary fibrosis.

Elimination

Once a drug is metabolised, it is important to know whether its metabolites are active or inactive, and what the physiological effects and half-life ($t_{1/2}$) of active metabolites are especially if their clearance route is compromised by organ failure.

Clearance

Clearance is the theoretical volume of blood or plasma that is completely cleared of drugs per unit time.

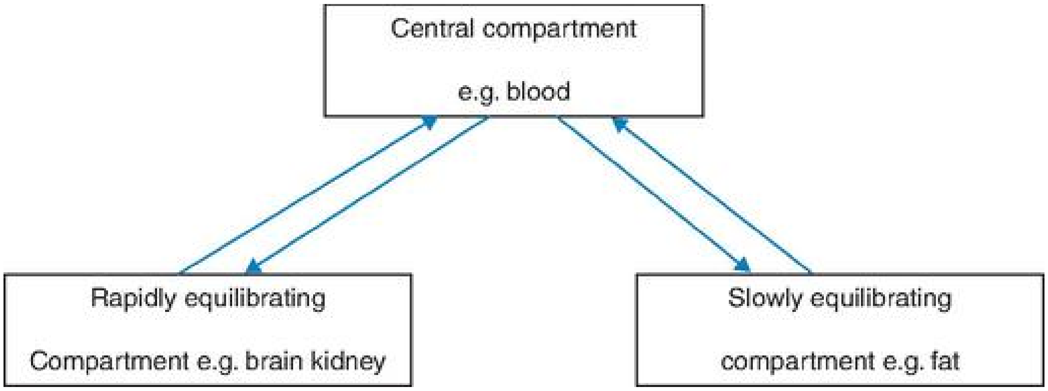
For the majority of drugs, the rate the liver or kidney can remove drug from the body is usually proportional to the concentration of drug in the blood (first-order kinetics). This proportionality constant is known as the drug's clearance (Cl).

Clearance is related to the half-life ($t_{1/2}$) of the drug.

Half-life is the time taken for the plasma drug concentration to fall by 50% and is dependent on V_d :

$$t_{1/2} = \frac{0.693 \times V_d}{Cl}$$

NB: alpha $t_{1/2}$ =distribution $t_{1/2}$ (initial decay $t_{1/2}$ – distribution of drug into tissue or slowly equilibrating second compartments in a two-compartment model. See Fig. 119.3).



The diagram displays a three-compartment model for drug distribution. The central compartment, labelled as blood, is positioned at the top and is connected by bidirectional arrows to two peripheral compartments. On the left, a rapidly equilibrating compartment is labelled with examples such as the brain and kidney. On the right, a slowly equilibrating compartment is labelled with fat as an example.

FIG. 119.3 **Compartment models.** The body is represented by a central compartment plus one or more peripheral compartments. Compartment models have limited use in predicting PK in the critically ill as blood flow is not taken into account and therefore physiology is highly variable. Elimination of drug occurs after equilibration in compartments. Hydrophilic drugs usually exhibit single-compartment PK; liophilic drugs exhibit two or three-compartment PK.

beta $t_{1/2}$ = terminal elimination $t_{1/2}$ (second decay $t_{1/2}$ usually represents elimination $t_{1/2}$).

Any process that reduces V_d without affecting clearance will shorten $t_{1/2}$ and vice versa.

Caution must be taken with interpreting half-lives with respect to a drug's duration of action. Simply using terminal elimination $t_{1/2}$ to predict the length of drug effect may not be accurate. For example unlike single-compartment hydrophilic drugs e.g. gentamicin, lipophilic fentanyl exhibits a three-compartment PK model following an IV bolus [21] :

1. *Short-distribution phase:* High concentrations are achieved rapidly in well-perfused organs (brain, kidneys, lungs)
2. *Slower redistribution phase:* In other tissues, skeletal muscle and fat
3. *Elimination phase:* The terminal $t_{1/2}$ is 3.7 hours, but the duration of action of fentanyl may vary due to 80% protein binding and redistribution into body compartments. Hepatic impairment prolongs $t_{1/2}$.

See Fig. 119.3 .

Steady State

$t_{1/2}$ can be used to predict the time for a drug to reach 'steady state', C_{ss} (i.e. when the rate of drug administration equals the rate of drug elimination), is usually reached within 4 or 5 half-lives. Similarly, the time taken for a drug to be eliminated from the body would also be 4 to 5 half-lives. [1]

Renal clearance of a drug or metabolite is influenced by glomerular filtration, tubular secretion and tubular reabsorption.

Glomerular filtration usually allows the passage of the free but not protein-bound drug into the renal tubules. Drugs that are not tubular secreted or reabsorbed therefore have a renal clearance that equals the glomerular filtration rate (GFR). Conversely, drugs that undergo active tubular secretion have higher renal clearances up to a theoretical maximum of renal blood flow. They are usually charged with a high affinity for transporter sites, allowing the passage of even protein-bound drugs. Tubular secretion normally occurs in the proximal tubule and is assumed if clearance rate exceeds calculated filtration rate.

Tubular reabsorption involves the passive diffusion of usually lipophilic and uncharged drugs back across the tubule into the systemic circulation. Extent of reabsorption is determined by the degree of ionisation (determined by urine pH) and the concentration gradient (determined by flow rate). Reabsorption is assumed if the clearance rate is less than the calculated filtration rate (e.g. fluconazole reabsorption is considerable in normal renal function but reduced in acute kidney injury; therefore dose reduction is not necessary, and even an increase may be warranted).

Augmented renal clearance (ARC; $C_r Cl \geq 130$ mL/min/1.73 m^2) and hepatic clearance can occur as a result of increased cardiac output, and therefore enhanced perfusion to the kidneys and liver by fluid resuscitation, inotropic support or the hyperdynamic phase of sepsis. This often results in increased metabolism and clearance of drugs. Young (<60 years old), surgical, trauma or burns patients with low sequential organ failure assessment (SOFA) scores (≤4) are particularly susceptible to ARC.[22]

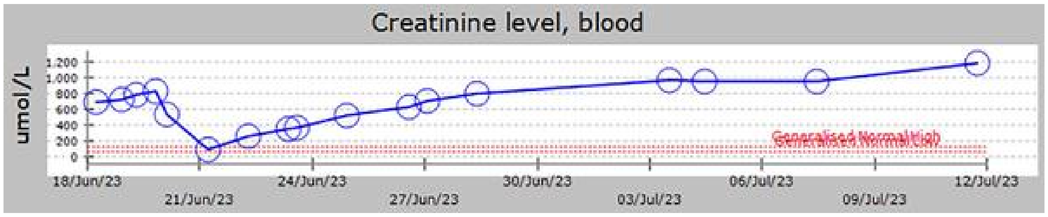
Renal Drug Clearance

Reduced renal drug clearance prolongs the terminal elimination $t_{1/2}$, leading to toxicity if dose adjustments are not made to account for the accumulation of drugs and their active metabolites cleared primarily by the kidneys. Dose can either be reduced, for instance vancomycin (time-dependent bacterial kill), or their dosing intervals increased, for instance, gentamicin (concentration-dependent kill). Renal failure usually affects glomerular function more than tubular function, so the excretion of aminoglycosides, which depend more on glomerular filtration, is affected more than that of penicillins, which are dependent on tubular function.

Serum creatinine is usually a poor marker of renal function in the critically ill[23] because creatinine is:

- a by-product of muscle often reduced as catabolism and severe muscle wasting can lead to a loss of up to a third of muscle mass within ten days of ICU inpatient stay[24]
- influenced by diet e.g. recent protein intake or insufficiency due to variable absorption[23]
- increased or reduced by drugs or disease states without necessarily influencing GFR (e.g. trimethoprim inhibits the renal secretion of creatinine without reducing renal clearance)[25]
- a very late marker of renal dysfunction; the GFR has to fall by at least 50% before a significant rise in creatinine is seen[26]

- usually fluctuating in the critically ill, together with the reasons described above cannot be used in creatine clearance (CrCl) calculations, which are based on a normal healthy population. More accurate biomarkers of renal function have been proposed e.g. soluble urokinase plasminogen activator [26] but are experimental and not readily available in most hospital laboratories. In practice, following upward trends in creatinine, renally cleared electrolytes (phosphate, potassium and magnesium) and drugs e.g. vancomycin and gentamicin together with reduction in urine output in adequately fluid-resuscitated patients can be early signs of deteriorating renal function (Fig. 119.4).



The two-part line graph tracks blood test results over time. The top graph shows creatinine levels in micromoles per litre from June 18 to July 12. Values start around 800, dip sharply below 200 by June 21, then progressively rise, stabilising above 600 from early July onward. The bottom graph plots inorganic phosphate levels in millimoles per litre over the same date range. Levels drop steeply from approximately 3 to near 1 millimoles per litre by June 21, then gradually rise with moderate fluctuations through July 12.

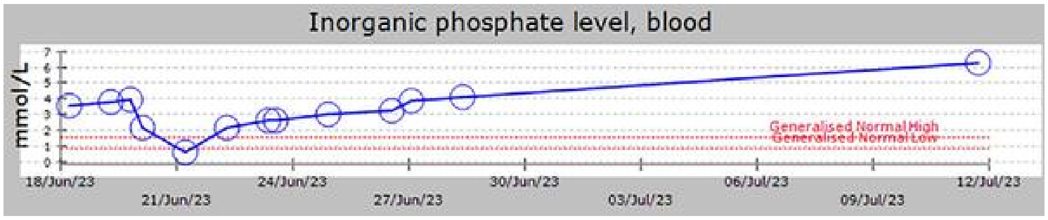


FIG. 119.4 Trend in renally cleared electrolyte in renal dysfunction mapped versus creatinine.

See Table 119.2 for other clearance routes.

Table 119.2

Other clearance routes

CLEARANCE ROUTE	MECHANISM OF ACTION	EXAMPLE
Biliary (affected by biliary obstruction)	Transported by hepatocytes, excreted in the bile either unchanged or conjugated. Conjugated molecules undergo enterohepatic recirculation (hydrolysed by gut bacteria, secreted into the ileum, reabsorbed into the systemic circulation and transported back to the liver via the portal vein).	Phenytoin [6] Loperamide [27]
Non-oxidative	Hydrolysis by non-specific blood esterases in the blood; Non-enzymatic pathway (Hofmann elimination) at physiological pH and body temperature; the elimination rate is increased at higher pH or temperatures and vice versa.	Atracurium [28]
Pulmonary	CYP enzymes though the levels are significantly lower compared to the liver. Little evidence they substantially contribute to systemic clearance but are first-line defence against pulmonary toxicity. [29]	

Pharmacodynamics

Pharmacodynamics (PD) is the pharmacological effect of a drug on the body, or in the case of antimicrobials, on the microbiological organism. For antimicrobials, PD refers to the ability of the drug to kill or inhibit the growth of the micro-organism, or even to suppress the emergence of resistance. Combined with PK, PK/PD then describes dose-response relationships. In the case of sedatives, PD describes the relationship between dose and the resulting degree of sedation in an individual. Many drugs have an 'end-of-needle' effect where, in the case of vasopressors, the effect of modulating doses is evident through observable changes in a patient's mean arterial pressure allowing the clinician to easily individualise a dose to a patient's needs at that moment in time. Other drugs require different information to optimise dosing, for example anti-coagulants such as an intravenous infusion of unfractionated heparin require activated patrial thromboplastin time (aPTT) biomarker monitoring. For other drugs (e.g. phenytoin and vancomycin), direct measurement of the blood concentration of the drug is necessary, along with dosing adjustment to ensure the measured concentration is within a 'therapeutic range' which is associated with a high likelihood of a good clinical outcome (a process known as therapeutic drug monitoring).

Drug dosing in critically ill patients can be challenging because of all the challenges described in the PK section above. However, PD considerations such as receptor binding or microbiological organism susceptibility to a drug can further change dosing requirements. Measurement of binding to target receptors in the body is not possible in clinical practice and as such requires a dose titration approach until therapeutic exposures (concentrations) are achieved (e.g. opioid analgesics for the relief of pain). Susceptibility of micro-organisms to an antimicrobial is most commonly described using a measure called a minimum inhibitory concentration (MIC), a test run in a microbiology laboratory over 16–20 hours, measuring the capacity of doubling dilutions of a drug to inhibit organism growth. The lowest concentration that inhibits visible growth is the MIC. In antimicrobial PK/PD, the MIC is the denominator in all PK/PD indices. For some antimicrobials, their effectiveness is best described by the free (unbound) peak concentration to MIC ratio (fCmax/MIC), others, the time that the free concentration exceeds the MIC throughout a dosing interval (f T>MIC) and finally those where the free area under the concentration-time curve to MIC (f AUC/MIC). These differing concentration-time curve profiles for different drugs mean that methods for dose optimisation will be different. For instance, for *f* Cmax/MIC giving these drugs in infrequent large doses will maximise achievement of peak concentrations (e.g. aminoglycosides dosed 24–48 hourly depending on renal function). Alternatively, high peak concentrations are not advantageous for *f* T>MIC drugs so giving these as a prolonged infusion (e.g. over 50%–100% of dosing interval) will maximise time above the MIC. As such, a knowledge of PD can help a clinician make sensible judgements about initial dosing, maintenance dosing and dosing adjustments to ensure drug exposures associated with a maximum likelihood of effectiveness are obtained.

See Table 119.3 .

Table 119.3

Examples of therapeutic drug monitoring (TDM)

DRUG	TDM RECOMMENDATION, SUGGESTED TDM SAMPLING AND TARGETS IN CRITICALLY ILL PATIENTS	TARGET
Aminoglycosides [30]	*AUC-based monitoring* Two samples: One taken 30 mins after the end of the infusion and the other one taken between 6 and 22 h post-infusion *C_{max}/MIC monitoring* One sample 30 min after end of infusion *C_{min} monitoring* One sample 30 min or just before the next dosing [a]	AUC: 80–120 mg h/L $C_{\text{max}}/\text{MIC} \geq 8\text{–}10$ C_{min} Amikacin <2.5 mg/L [a] Gentamicin/tobramycin <0.5 mg/L [a]
Vancomycin [30]	*AUC/MIC based monitoring* Two samples: One taken 1 h after the end of the infusion and the other one taken within 1–2 h of the next infusion [a] C_{min} monitoring	$\text{AUC}_{0\text{-}24}/\text{MIC} \geq 400$ C_{min} >10 mg/L [a] C_{min} ≥15–20 mg/L (severe infections) C_{ss} 20–25 mg/L

DRUG	**TDM RECOMMENDATION, SUGGESTED TDM SAMPLING AND TARGETS IN CRITICALLY ILL PATIENTS**	**TARGET**
	One sample 30 min or just before the next dosing [a] C_{ss} monitoring for continuous infusion One sample at any point during infusion	
Phenytoin [1]	C_{min} *monitoring assuming* C_{ss} *achieved* One sample just before the next dosing	C_{min} = 10–20 mg/L (corrected for hypoalbuminaemia)
Digoxin [2]	C_{max} *dosing* One sample at least 6 h post dose	C_{max} = 1–2 mcg/L (sample only taken to exclude lack of absorption when orally administered or toxicity). It is not used to assess efficacy, e.g. when used for rate control in atrial fibrillation a low digoxin level but a normal heart rate would not warrant an increase in dose.

[a] Please consult your local guidelines as sampling, turnaround times and, therefore target concentrations may differ.

Summary

PK and PD are neither simple nor straightforward, and rarely does one dosage regimen fit all. To ensure best practice and avoid any unnecessary harm to patients, it is wise to involve an ICU pharmacist in drug dosing decisions.

Sedation and pain management in intensive care

Luke Torre and Elizabeth T. Tran

Despite the widespread use of sedative and analgesic agents in the intensive care unit (ICU), goals of sedation and analgesia are not well established. [1] Having its roots in anaesthesia, ICUs would historically manage patients with full general anaesthesia, including skeletal muscle paralysis and controlled ventilation modes, and this was maintained until the disease process remitted. Sedation and analgesia were considered a necessary adjunct to the management of critically ill patients.

Combinations of opioids and benzodiazepines are commonly used to provide ‘sedation’ in the ICU. Because high doses of opioid analgesics may themselves result in significant sedation and are synergistic with sedative agents, the distinction between sedation and analgesia is blurred.

Sedation

There has been a paradigm shift in thinking towards sedation practice in ICUs over the past 30 years. A combination of factors has led to this change, notably:

- improved ventilator technology and ventilation modes allowing synchronised and spontaneous respiration
- improved drug development; with pharmacokinetic profiles that allow prompt titration, and pharmacodynamic profiles with fewer side effects

- the development and implementation of sedation scoring systems in the ICU [2]
- the increasing use of percutaneous tracheostomy, non-invasive ventilation and high-flow nasal oxygen for patients requiring respiratory support
- the recognition of critical illness polyneuropathy and myopathy and their associated risk factors
- the separation and specialisation of intensive care physicians from other domains
- the emerging high-quality evidence in the field of sedation and analgesia in intensive care
- economic pressures and increased demand for finite intensive care resources.

Currently, sedative use in the critically ill should be for one or more of the following purposes:

- a treatment for disease processes such as seizures, raised intracranial pressure, serotonin syndrome and alcohol withdrawal
- to facilitate tolerance of intensive care therapies such as endotracheal intubation, mechanical ventilation and active cooling
- to reduce oxygen consumption by reducing patient arousal, activity and anxiety
- to maintain the safety of patients and carers dealing with the hyperactive delirious patient
- procedural sedation
- palliation.

Sedation of patients in the ICU is an integral part of what health care workers perceive to be care and compassion for the critically ill patient. Presumed benefits of sedative agents include:

- reducing patient anxiety over their illness, the welfare of relatives or the risk of death
- providing adequate rest

- reducing the distress of unpleasant sensations, invasive treatments and monitoring
- blunting awareness of the environment over which the patient has minimal control and in which they may be unable to communicate.

Non-pharmacological methods should preferentially be used to help manage these issues. Avoiding potentially distressing situations, allowing adequate access to caring visitors, maintenance of good communication with the patient and having a positive outlook by carers will satisfy many of these goals. Small comforts, such as ice chips by mouth, a comfortable mattress, relaxation music and maintaining a daytime/nighttime environment all help this process.

Level and Assessment of Sedation

Critical to delivery of sedation is an accurate sedation assessment tool. Sedation scoring systems were first introduced in the 1970s. [2] Since that time, several validated scoring systems for critically ill patients have become available. The Ramsay Sedation Scale (RSS) and Richmond Agitation Sedation Scale are two of the most popular used worldwide (Tables 120.1 and 120.2). Despite their availability, validation and evidence base, their incorporation into routine management of intensive care patients remains low. [3]

Table 120.1

Table 120.2

Richmond agitation sedation scale

POINT	PATIENT RESPONSE TO VERBAL AND PHYSICAL STIMULI
+4	Combative – combative, violent, immediate danger to staff
+3	Very agitated – pulls or removes tubes or catheters; aggressive
+2	Agitated – frequent non-purposeful movement, fights ventilator
+1	Restless – anxious, apprehensive but movements not aggressive or vigorous
0	Alert and calm
−1	Drowsy – not fully alert, but has sustained (>10 s) awakening (eye opening/contact) to voice
−2	Light sedation – drowsy, briefly (<10 s) awakens to voice or physical stimulation
−3	Moderate sedation – movement or eye opening (but not eye contact) to voice
−4	Deep sedation – no response to voice but movement or eye opening to physical stimulation
−5	Unarousable – no response to voice or physical stimulation

From Siegel MD. Management of agitation in the intensive care unit. *Clin Chest Med* . 2003;24(4):713–722.

Electroencephalography (EEG), which may be either ‘raw’ or ‘processed’, provides a measure of cerebral activity. This monitor is more suitable for assessing depth of anaesthesia and may be difficult to interpret in the encephalopathic patient. Devices using integrated EEG (e.g.

bispectral index [BIS]) are available, but further research is required to establish their role in the ICU. [4]

Sedation Strategies

Although the choice of sedative agent(s) must be a conscientious decision based on pharmacokinetic and pharmacodynamic factors relevant to the critically ill patient, it is perhaps of greater importance to decide on the sedation strategy used.

A variety of strategies have been described:

- goal-directed sedation and early goal-directed sedation
- patient-targeted sedation protocols
- daily interruption of sedation
- intermittent sedation
- ‘analgosedation’, or analgesia-first sedation
- ‘nonsedation’
- patient-controlled sedation.

The purpose of these strategies should be to achieve a controlled and predetermined level of sedation in the patient. The chosen level of sedation will be intimately linked to the underlying disease process, patients' characteristics and the treatments and interventions they are receiving. The aim of sedation should be documented by the team and conveyed to the bedside nurse, who will have the largest impact on achieving and maintaining the chosen level. Once instituted, the level of sedation should be regularly assessed.

Goal-directed sedation was the first method described in which sedatives are freely adjusted (usually by the bedside nurse) to attain a prescribed level of sedation from a sedation scoring system. [2] A recent focus is on ‘early goal-directed sedation’, emphasising sedation titration from its commencement in the ICU. This has stemmed from prospective cohort studies showing worse outcomes (including mortality) in patients with deeper levels of initial sedation. [5], [6] *Patient-targeted sedation protocols* implement two main features: a structured approach to the assessment of patient pain and distress, coupled with an algorithm that directs drug escalation and de-escalation based on the assessments.[7]

Daily interruption of sedation: this strategy uses a similar goal of sedative and analgesic titration to a desired depth of sedation. In contrast to 'patient-targeted sedation protocols', no formal algorithm has been established for drug escalation. However, the risk of excessive sedation is minimised by a daily interruption of both sedative and analgesic infusions until the patient awakens or exhibits distress that mandates drug recommencement, usually with an initial bolus followed by a reduced infusion rate.[7]

Intermittent sedation administration involves the use of longer-acting sedative agents, typically lorazepam, given by intermittent bolus titrated via a sedation scoring system.

'Analgosedation', or analgesia-first sedation, is a more modern approach gaining favour in patients, especially where sedation is not a treatment of their disease process. In these patients, opioid analgesia is instituted first (usually a remifentanil infusion), and after the pain is adequately controlled, verbal measures are used to calm the patient to a targeted sedation level (e.g. Ramsay score 3–4). Major tranquilisers (e.g. haloperidol) are given for delirium, and only then are sedative agents (e.g. propofol) used for short-term infusion and promptly ceased.[8]

'Nonsedation', similar to analgosedation, involves intermittent opioid administration (e.g. morphine) and non-pharmacological methods to calm patients, to avoid pharmacological sedative use in selected patients. Outcomes are similar to daily interruption of sedation.[9]

Proposed benefits of sedation strategies include[7–14]:

- shorter duration of mechanical ventilation
- shorter length of ICU and hospital stay
- economic benefit
- less need for diagnostic studies (e.g. computed tomography [CT] scans) to assess impaired conscious state
- less ventilator-associated pneumonia

- a possible mortality benefit.

Criticisms of these strategies include:

- high self-extubation rates
- promotion of myocardial ischaemia
- triggering of a withdrawal syndrome.

Concerns over increased long-term neuropsychological effects (e.g. post-traumatic stress disorder) have been unfounded. Instead, evidence suggests a reduced incidence using such strategies.[15, 16]

Sedation and analgesia patient care ‘bundles’ have emerged, attempting to improve ICU outcomes. These provide a comprehensive holistic patient management plan addressing sedation and analgesia at multiple levels. For example, the ‘ABCDEF bundle’ combines daily; interruption of sedation, spontaneous breathing trial, pain assessment and management, delirium assessment and management, early mobilisation package and family empowerment, aiming to optimise resource utilisation and reduce the incidence of ICU-acquired delirium and weakness.[17, 18]

Sedative Agents

GABA-A Receptor Agonists

Gamma-aminobutyric acid (GABA) is a major neurotransmitter in the central nervous system involved in the complex process of sedation. It binds to the alpha subunit of the GABA-A receptor and, by activation, causes a conformational change that opens the ligand-gated channel, allowing chloride ion influx into the neuron. This hyperpolarises the neuronal membrane and reduces neuronal activity resulting in sedation.[19]

The GABA-A receptor agonists used in intensive care are benzodiazepines, propofol and barbiturates. They all share amnesic, hypnotic, anxiolytic and anticonvulsant effects but have no analgesic properties.

Benzodiazepines

Benzodiazepines, as a class, are widely used sedatives in ICUs. Benzodiazepines are good anticonvulsant drugs and provide some muscle relaxation. They bind to the gamma subunit of the GABA-A receptor, resulting in a conformational change causing increased opening frequency of the channel. [20] The commonest agents used worldwide are midazolam, lorazepam and diazepam.

These drugs may be given by many routes but most commonly intravenously (IV) or orally (PO). IV administration is by either continuous or intermittent IV infusion (e.g. midazolam in 1 mg/mL, titrated to effect).

Dosage of these agents may vary widely depending on various pharmacokinetic and pharmacodynamic factors such as:

- prior exposure to benzodiazepine (increased tolerance)
- age and physiological reserve
- volume status (hypovolaemic patients are more sensitive)
- renal and hepatic dysfunction
- co-administered drugs (e.g. combined with an opioid)
- history of alcohol consumption (increased tolerance).

Although some benzodiazepines (e.g. midazolam) are short-acting, water-soluble agents, there is potential for accumulation of both parent compound and active metabolites in patients with hepatic and/or renal dysfunction. Midazolam, for example, is rapidly metabolised by cytochrome P450 3A to its major active metabolite α1-hydroxymidazolam. This is then conjugated with glucuronide and excreted in the urine. [21] In the critically ill, for whom there may be extensive derangement of benzodiazepine pharmacokinetic profiles, midazolam may result in prolonged sedation with increased length of mechanical ventilation and ICU stay. [22,23] Therefore predetermining suitable dosages is difficult. Midazolam 0.02–0.2 mg/kg/h may be suitable, with the level titrated to individual response. Longer-acting agents, such as diazepam, may be given by intermittent IV injection (e.g. diazepam 5–10 mg) as necessary.

Benzodiazepines are often combined with opioids in a compound ‘sedative’ infusion. This allows lower doses of benzodiazepine to be used, while benefiting from the opioid effects of respiratory and cough suppression, to facilitate mechanical ventilation and endotracheal tube tolerance.

Flumazenil (flumazepil), the specific benzodiazepine antagonist, may be used to reverse the effect of benzodiazepines to counter unwanted acute side effects, such as severe hypotension or respiratory depression, or to allow acute neurological assessment.

Propofol

The IV anaesthetic agent propofol (2,6-di-isopropylphenol) is frequently used for sedation in the ICU. It binds to the beta subunit on the receptor and causes a conformational change to the chloride channel. [20] It gives more profound hypnosis than benzodiazepines, which have a ceiling effect. It is given by continuous IV infusion.

Propofol has a favourable pharmacokinetic profile compared with benzodiazepines, due to rapid hepatic and extrahepatic conjugation reactions to inactive metabolites. Indeed, clearance of propofol exceeds hepatic blood flow. This gives it a relatively short context-sensitive half-time, resulting in rapid offset, including after prolonged infusion.

Compared to benzodiazepines (specifically midazolam), propofol has been shown to reduce time on mechanical ventilation, time to extubation and ICU length of stay in elective surgical patients; while reducing time to extubation in critically ill medical and surgical patients. [24-26]

Caution is required in hypovolaemic patients or those with impaired myocardial function because severe hypotension may result. [27] Doses for ICU sedation are generally much lower than those required for anaesthesia. The diluent in which propofol is delivered is lipid rich and should be considered a source of nutrition and indeed cause of hyperlipidaemia, depending on dosage and duration of therapy. Disodium edetate, present in the propofol solution, does not appear to be harmful in patients receiving long-term infusions of propofol. [28]

There continues to be concern about propofol infusion syndrome (PRIS) which, although rare, has a high mortality. The first reported case series in 1992 were five children aged six or less, in the United Kingdom, all of whom died unexpectedly after being mechanically ventilated for upper respiratory tract infections causing stridor and distress. [29] Propofol, a relatively new agent at the time in ICU, was given in each case at a dose above 4 mg/kg/h for greater than 48 hours. The case report meticulously documented the strikingly similar presentation in each child: progressive lactic acidosis, cardiovascular instability, bradycardia and eventual cardiac arrest. Lipaemia, high fever, renal failure and hepatic enlargement were also noted. Post-mortem examinations showed features of myocytolysis, cerebral oedema and fatty infiltration of the liver. The condition is now well recognised in adults with a similar clinical course. [30] Rhabdomyolysis has been observed and confirmed post-mortem. [31] The risk factors for PRIS are shown in Table 120.3 . [32]

Table 120.3

Risk factors for Propofol Infusion Syndrome [32]

RISK FACTORS
Paediatric patients
Doses >4mg/kg/h for >48 hours
Severe head injuries
Septic shock
High exogenous or endogenous catecholamine levels
High exogenous or endogenous glucocorticoid levels
Inborn errors of metabolism
Low carbohydrate intake

Adapted from Mirrakhimov AE, Voore P, Halytskyy O, Khan M, Ali AM. Propofol infusion syndrome in adults: a clinical update. *Crit Care Res Pract* . 2015;2015:260385.

The pathophysiology of PRIS is complex, multifaceted and incompletely understood. [30] , [33] , [34] Propofol and its metabolites may impair multiple steps in the mitochondrial electron transport chain, uncoupling oxidative phosphorylation, preventing ATP production and leading to intracellular acidosis. [35-37] Propofol also impairs free fatty acid (FFA) oxidation in mitochondria, and the resultant increase in FFA concentration directly impairs the electron transport chain. The high FFA load delivered by the soybean extract in propofol may exacerbate this effect. [38], [39] There may also be a genetic susceptibility. [40] Propofol inhibits cardiac beta-adrenoceptor binding and calcium channel protein function. [41] ECG changes of right bundle branch block and a 'Brugada like' pattern (coved ST segment elevation followed by an inverted T wave) may occur in PRIS. [30] Caution should be exercised when using propofol for prolonged periods (>48 hours), and infusion rates should be kept below 4 mg/kg/h. Monitoring serum triglycerides, lactate and CK should be considered in patients at risk. [42] Management requires immediate cessation of propofol, institution of cardiovascular supports (which may necessitate extra-corporeal membrane oxygenation (ECMO)), and haemodialysis. [37]

Barbiturates

Thiopentone is reserved for specific indications, such as management of intractable intracranial hypertension, or for the treatment of status epilepticus. It is not commonly used as a general sedative agent due to a long context-sensitive half-time when given by continuous infusion.

Volatile Anaesthetic Agents

The use of volatile anaesthetic agents for sedation in the ICU has been limited by:

- the cost of prolonged administration
- the more complex setup required for the administration of these agents (vaporiser, scavenging apparatus etc.)
- specific side effects, such as fluoride ion accumulation and consequent renal dysfunction (sevoflurane [fluoromethyl hexafluoroisopropyl ether] and isoflurane), compound A accumulation and possible renal dysfunction (sevoflurane and absorbent interaction)

- occupational health and safety concerns (e.g. spontaneous miscarriage)
- environmental concerns

Isoflurane and sevoflurane provide hypnosis, amnesia and, at higher concentrations, immobility of the patient. They have no analgesic properties. Their mechanism of action remains hotly debated and unconfirmed. Desflurane, due to its low boiling point, has not yet been successfully incorporated into intensive care ventilator systems.

Volatile agents are useful for short periods of anaesthesia during invasive procedures in the ICU. They have classically been used for longer periods of sedation in acute severe asthma due to their bronchodilator effect.

Newer vaporiser systems, such as the Sedaconda ACD, allow safe administration of volatile agents through a standard ICU ventilator. Incorporating a carbon filter, the device allows approximately 90% of the volatile agent to be recirculated, reducing volatile usage and cost.[43]

Studies generally show a reduced time to extubation and duration of mechanical ventilation with volatile agents compared with GABA-A agonists, with the time benefit being greater as the duration of sedation increases.[43-45] Other potential advantages include:

- lack of withdrawal syndrome
- predictable offset independent of renal or hepatic dysfunction
- cardioprotective effects
- no tachyphylaxis
- lower incidence of delirium
- ability to measure and titrate end-tidal volatile concentration.

N-methyl-d-aspartate Receptor Antagonist

Ketamine acts by blocking *N*-methyl-d-aspartate (NMDA) receptors. It produces a sedative state known as ‘dissociative anaesthesia’, with the following characteristics:

- mild sedation
- amnesia

- analgesia
- reduced motor activity.

The lack of respiratory and cardiovascular depression at lower doses makes this a relatively safe drug in the ICU. Limitations to its use include hallucinations, and delirium during the recovery/withdrawal phase. These may be ameliorated by benzodiazepine or dexmedetomidine administration.[46] Ketamine may be used specifically for sedation in severe asthmatics (for its bronchodilator effect), in patients following head injury (for its effect at the NMDA receptor) or in patients where analgesia is difficult (e.g. extensive burns).[47], [48] Its use is also described for intubating patients who are hemodynamically unstable.

α_2-Agonists

Dexmedetomidine is increasingly popular in ICU sedation, as a single agent or combined with an IV analgesic, particularly in patients weaning from mechanical ventilation. A highly selective alpha-2 agonist that causes hyperpolarisation of the presynaptic membrane in central alpha–2 receptors, it reduces release of noradrenaline at these terminals.[49] This results in a sedative effect that resembles natural sleep, sympatholysis and centrally mediated analgesia. Additionally, there appears to be a poorly defined pathway of imidazoline receptor activation contributing to the analgosedation.[50]

Dexmedetomidine has several advantages including[49,51]:

- Reduced duration of mechanical ventilation
- Reduced ICU length of stay
- Minimal depression of respiratory drive and airway reflexes
- Reduction in dosage of co-administered benzodiazepines or opioids
- Less risk of withdrawal syndromes

Studies have not demonstrated any significant effect on ICU mortality.[51], [52] There has been concern over a trend towards increased mortality in the <65 age group; however, further studies are needed.[53] Current evidence suggests overall the incidence of delirium is reduced with dexmedetomidine; however, this appears to vary between different cohorts of patients.[52-54]

For example, no benefit was seen with dexmedetomidine compared to propofol in critically ill ventilated patients with sepsis.[52] Adverse effects are largely cardiovascular and include bradycardia and hypotension.[49,55] Caution has been advised in patients at risk of bradyarrhythmias or heart block, patients with untreated hypotension or acutely post high-risk cardiac surgery.

Continuous infusion rates are titrated between 0.2 and 1 µg/kg/h to achieve desired effect, with effective dosing occasionally limited by cardiovascular instability. A loading dose of 1 µg/kg over 10 minutes is recommended in healthy patients, but this should be avoided or attenuated in the critically ill. Extubation is usually performed with the agent still infusing to maintain the tranquil cooperative state. While initially approved for a 24-hour duration of use, an acceptable safety profile has been proven to be 30 days.

Clonidine, an established long-acting α_2-agonist, may be used to enhance sedation and analgesia when GABA-A agonists and opioids are used. It can be delivered via oral or intravenous routes. The usual dose range is 50–150 µg, 4–6 hourly.

Analgesia

Pain management is a priority in the care of critically ill patients. Skilled use of analgesics in the modern ICU aims to ensure that patients no longer suffer pain. Pain management requires a comprehensive assessment and management model involving non-pharmacological and pharmacological techniques.

Many patients present to the ICU with painful conditions or undergo painful procedures during their stay. Patients commonly report pain from routine ICU procedures like arterial and central venous cannulation, endotracheal suctioning, insertion of an indwelling urinary catheter or nasogastric tubes and even turning in bed.[56] In addition, other adverse symptoms commonly reported include unsatisfied thirst, difficulty sleeping, anxiety, unsatisfied hunger, depression and shortness of breath.[56]

Pain has multiple adverse consequences, such as:

- provoking anxiety
- interrupting sleep
- worsening delirium
- increasing the stress response
- causing respiratory embarrassment due to atelectasis and sputum retention
- causing immobility with venous and gut stasis.

Pain management comprises many modalities in addition to pharmacological methods, including:

- a caring and supportive ICU team, whom the patient can trust
- warm and comfortable surroundings
- attention to pressure areas
- bowel and bladder care
- adequate hydration and amelioration of thirst (e.g. moistening the mouth)
- early tracheostomy, where indicated, to reduce the discomfort of endotracheal intubation
- supplemental treatments such as acupuncture, acupressure, massage and transcutaneous electrical nerve stimulation (TENS).

Accurate and structured pain assessment is an important part of ICU patient management. For the patient who can communicate, self-reporting remains the gold standard. For those unable to self-report, a variety of pain assessment tools are available, some tailored specifically to critically ill patients. The Behavioural Pain Scale (BPS) (Table 120.4) and Critical-Care Pain Observation Tool (CPOT) (Table 120.5) are well-validated in adult ICU patients. [57-61] The use of vital signs and physiological markers alone to assess pain, and response to analgesic administration are unreliable.

Table 120.4

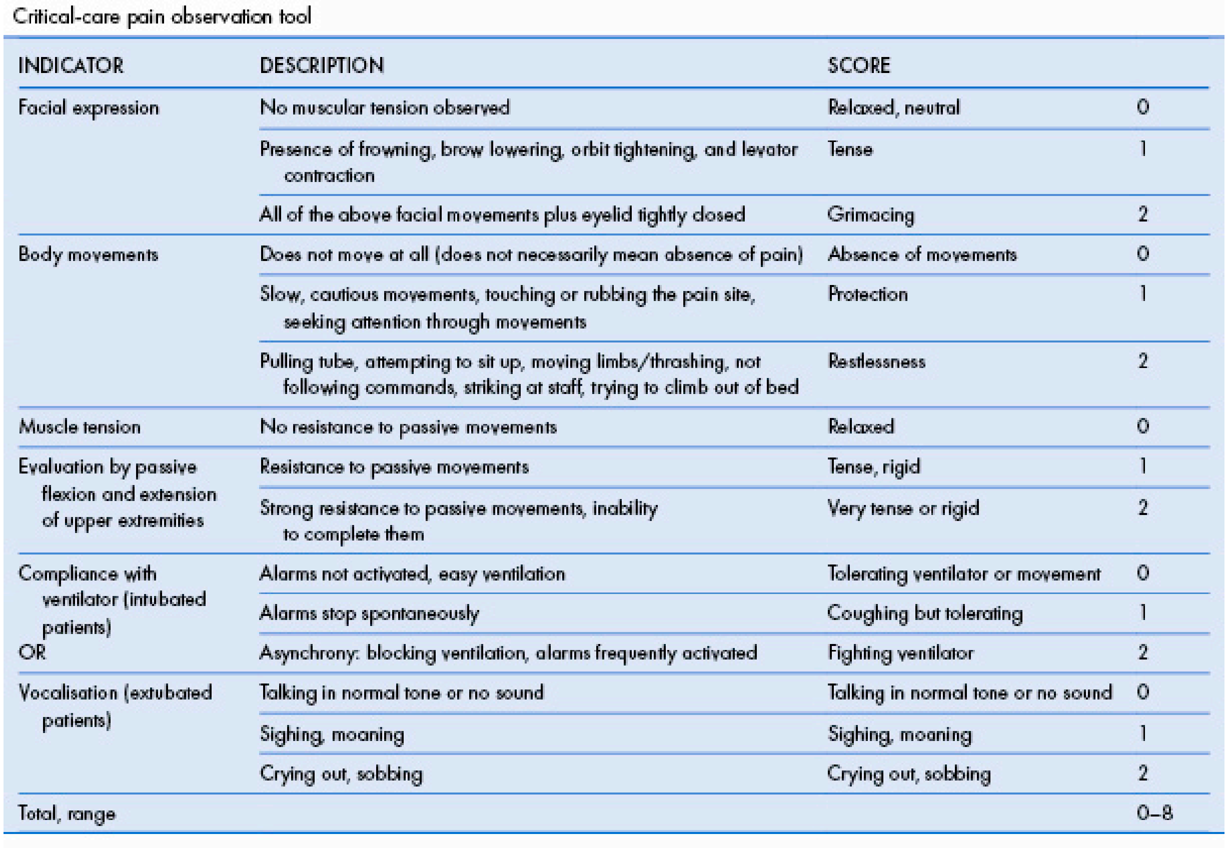
Behavioural pain scale

ITEM	DESCRIPTION	SCORE
Facial expression	Relaxed	1
	Partially tightened (e.g. brow lowering)	2
	Fully tightened (e.g. eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

Payen JF, Bru O, Bosson JL, et al. Assessing pain in critically ill sedated patients by using a behavioral pain scale. *Crit Care Med* . 2001;29(12):2258–2263.

Adapted from Young J, Siffleet J, Nikoletti S, et al. Use of a behavioural pain scale to assess pain in ventilated, unconscious and/or sedated patients. *Intensive Crit Care Nurs.* 2006;22(1):32–39; Elsevier 2006.

Table 120.5



Critical-care pain observation tool

INDICATOR	DESCRIPTION	SCORE	
Facial expression	No muscular tension observed	Relaxed, neutral	0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense	1
	All of the above facial movements plus eyelid tightly closed	Grimacing	2
Body movements	Does not move at all (does not necessarily mean absence of pain)	Absence of movements	0
	Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements	Protection	1
	Pulling tube, attempting to sit up, moving limbs/thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness	2
Muscle tension	No resistance to passive movements	Relaxed	0
Evaluation by passive flexion and extension of upper extremities	Resistance to passive movements	Tense, rigid	1
	Strong resistance to passive movements, inability to complete them	Very tense or rigid	2
Compliance with ventilator (intubated patients)	Alarms not activated, easy ventilation	Tolerating ventilator or movement	0
	Alarms stop spontaneously	Coughing but tolerating	1
OR	Asynchrony: blocking ventilation, alarms frequently activated	Fighting ventilator	2
Vocalisation (extubated patients)	Talking in normal tone or no sound	Talking in normal tone or no sound	0
	Sighing, moaning	Sighing, moaning	1
	Crying out, sobbing	Crying out, sobbing	2
Total, range			0–8

Opioids

Opioids remain the mainstay of analgesia in the ICU. Worldwide, the most commonly used agents in the ICU include:

- morphine and its analogues (e.g. diamorphine and codeine)
- semisynthetic and synthetic agents:
    - phenylpiperidine derivatives (e.g. pethidine, fentanyl, sufentanil and remifentanil)

    - methadone
    - thebaine derivatives (e.g. buprenorphine and oxycodone).

The effects of opioids are mediated via the five opioid receptor types; mu, kappa, delta, nociceptin and zeta. [62] These are G protein-coupled receptors, widely distributed throughout the central and peripheral nervous system, using various intracellular signalling pathways to cause analgesia. [63] Opioid side effects are well described.

Opioids are titrated to effect by intermittent IV injection, or by continuous infusion. This may be controlled by the nurse (nurse-controlled analgesia [NCA]) or by the patient (patient-controlled analgesia [PCA]). Suitable regimens are 1 mg/mL of morphine, 20 µg/mL of fentanyl or 200 µg/mL of hydromorphone titrated to effect.

NCA is often combined with a benzodiazepine such as midazolam to produce a ‘sedative/analgesic’ infusion for patients on mechanical ventilation (see Sedation section). Opioids can also be administered via the subarachnoid, epidural, transdermal, oral, sublingual and intranasal routes.

In the critically ill, the use of opioids may be complicated by:

- wide interindividual response to similar dosages, especially in debilitated and elderly patients.
- hypotension following rapid administration, particularly in hypovolaemic patients
- prolonged duration of action, due to accumulation of parent compound and metabolites (e.g. morphine and its major metabolites morphine-3-glucuronide and morphine-6-glucuronide) in the elderly and in patients with renal and hepatic dysfunction. Use of drugs with shorter half-lives (e.g. fentanyl or sufentanil) or those with organ-independent metabolism (e.g. remifentanil) can reduce this problem
- constipation, often requiring concomitant administration of aperients to promote regular evacuation and prokinetics to prevent gastrostasis and allow enteral feeding
- the development of tolerance
- nausea and vomiting

- an inability to administer slow-release preparations in the sedated patient as they cannot be crushed for delivery via an enteral feeding tube
- withdrawal

Recognition of withdrawal symptoms may be difficult in ICU patients because they may mimic sepsis or delirium. Treatment is by reinstitution and then slow withdrawal of the opioid. Alternatively, symptoms may be controlled by substitution for a long-acting opioid (e.g. methadone), benzodiazepines or α_2-agonists.

Delirium caused by opioid use in ICU patients is important to acknowledge.[64] Both pain and opioids can precipitate delirium, therefore control of pain but judicious use of opioids, in combination with other adjunctive techniques, is imperative.

In recent years, it has been recognised that opioids increase risk of serotonin syndrome when co-administered with other serotonergic agents. Proposed mechanisms for this action include both a weak serotonin reuptake inhibition and increased release of intrasynaptic serotonin.[65] The list of opioids associated with serotonin syndrome continues to grow and includes fentanyl, methadone, tramadol and buprenorphine.

The specific opioid antagonist naloxone has little role to play in the ICU, except for the treatment of severe hypotension, unwanted sedation or respiratory depression following opioid use or overdose. Rapid reversal of opioid effect to facilitate neurological assessment may be another valid use.

Remifentanil

This is a synthetic, selective mu receptor agonist. It undergoes organ-independent hydrolysis by plasma, red blood cells and tissue esterases. It has a reliable context-sensitive half-time of 4 minutes, which makes it particularly attractive for critically ill patients.

Although an analgesic, it is gaining favour as a sedative agent in intensive care because it causes sedation, tube tolerance and a slowed respiratory rate. In addition, its pharmacokinetic profile makes it ideal for rapid neurological assessment. Studies show reduced extubation times and ICU length of stay when compared with traditional opioids.[13-14]

The loading dose is usually 1 μg/kg; however, this should be avoided or attenuated in critically ill patients. Continuous infusion rates of 0.05–0.5 μg/kg/min are usually required, and a starting rate of 0.1 μg/kg/min is recommended. Dosage alterations are usually in increments of 0.025–0.1 μg/kg/min. Due to the short half-life, adequacy of response can be assessed within 20 minutes.

Weaning should also be done by incremental dose reductions due to the risks of rebound hyperalgesia. Adding ketamine during the weaning process may modulate this risk. [66]

Simple Analgesics

Paracetamol and other simple analgesics (e.g. salicylates) are particularly effective for:

- musculoskeletal pain
- perioperative pain
- inflammatory conditions
- multimodal analgesia, to reduce opioid requirements.

These drugs are given PO, per rectum (PR) or IV to supplement analgesia in the critically ill (e.g. paracetamol 1 g 4–6-hourly). Paracetamol use is limited by the risk of hepatic dysfunction if used in high doses or for prolonged periods.

Non-steroidal Anti-inflammatory Drugs

The commonly used non-steroidal anti-inflammatory drugs (NSAIDs) are carboxylic acids (e.g. indometacin [indomethacin], ibuprofen, mefenamic acid) or enolic acids (e.g. piroxicam). NSAIDs are useful for supplemental/multimodal analgesia in the ICU for the conditions listed previously for simple analgesics. They are given PO, PR or IM injection (e.g. indomethacin 100 mg twice daily PR). Patient selection is paramount in the critically ill due to their serious side effects, including:

- renal dysfunction

- gastrointestinal haemorrhage
- increased bleeding tendency due to platelet inhibition.

The newer cyclooxygenase-2 specific (COX-2) inhibitors, such as valdecoxib and its injectable precursor parecoxib, have a lower side-effect profile than traditional NSAIDs. This group of drugs should be used for only short periods due to an increased cardiovascular morbidity associated with long-term use. [67] COX-2 inhibitors should be avoided in post-operative cardiac surgical patients due to an increased incidence of thromboembolic complications and sternal wound infection. [68] , [69]

Tramadol

Tramadol is a synthetic, racemic preparation with multiple analgesic actions. The (+) enantiomer is a mu receptor agonist and serotonin reuptake inhibitor, whereas the (−) enantiomer is a norepinephrine reuptake inhibitor. [70] In addition to mu receptor action, which accounts for approximately 30% of its analgesic effect, it also enhances the descending inhibitory pathways involved in pain modulation. [71] It is useful for moderate to severe pain in the post-operative patient in doses of 50–100 mg IV, PO or IM 4-hourly to a maximum of 600 mg/day. Patients are at risk of developing serotonin syndrome while taking tramadol in combination with other proserotonergic agents. [72]

Tapentadol

Tapentadol is a centrally acting, synthetic analgesic with mu receptor agonism and norepinephrine reuptake inhibition. Its serotonin reuptake inhibition is minimal, it does not require metabolic activation and has no active metabolites. It is predominately conjugated by the liver and undergoes minimal cytochrome P450 enzymatic metabolism, thus reducing potential drug interactions. [73] , [74] It is useful for moderate to severe pain in doses of 50–100 mg IV or PO 4-6 hourly. Compared to tramadol, it has a more potent in vivo analgesic effect. [75] Comparing their adverse effects, tapentadol causes more constipation and respiratory depression but has a lower incidence of nausea and vomiting.[75] Despite the relative lack of serotonergic activity, case reports of serotonin syndrome involving tapentadol in combination with other proserotonergic agents have been reported.[74]

Ketamine

(See ‘NMDA receptor antagonist’ earlier.) Ketamine is commonly used as part of multimodal analgesic regimens in surgical patients with severe pain, or if tolerant to opioids. Continuous infusion in a dosage range of 0.1–0.2 mg/kg/h is recommended. Lozenges (50 mg) may be useful for short painful procedures (e.g. burn dressings). Intranasal esketamine, the S-enantiomer of racemic ketamine, is a recent option showing promise.[76]

Nitrous Oxide

Short-term administration of Entonox (50% nitrous oxide in oxygen) is still useful for analgesia during painful procedures (e.g. burns dressings). This may be given by demand valve (controlled by the patient) or be administered by the medical staff.

Local Anaesthetics – Regional Analgesia

The use of local anaesthesia for regional analgesia in the critically ill patient is limited by:

- pain often emanating from multiple sources and therefore not amenable to a single regional technique
- the requirement for IV sedation/analgesia (for reasons previously outlined), making a regional technique for pain superfluous
- the need to treat pain over a prolonged period, mandating either repetition of the regional block or the placement of an indwelling catheter (e.g. epidural catheter). Indwelling catheters have a defined duration of insertion (usually 3–4 days) due to increasing infection risk

- coagulopathy and thrombocytopenia, frequently seen in this group of patients, making procedures such as epidural injection less safe.

When a regional analgesic technique is considered viable, then the following needs to be considered:

- the availability of an adequately trained proceduralist
- regional techniques may be time consuming and require additional staff to position the patient and assist the proceduralist
- regional techniques carry serious complications (e.g. subarachnoid injection of local anaesthetic or epidural haematoma during placement of epidural catheters), as well as the risk of local anaesthetic toxicity
- good preparation is paramount:
  - informed consent from patient or legal surrogate
  - recent normal coagulation profile or correction of abnormal profile. Platelet counts greater than 75,000/µL are recommended and antiplatelet agents (other than aspirin) should be ceased at an appropriate time interval beforehand
  - the knowledge of and ability to deal with complications
  - experience and knowledge of the drugs being used. Typically ropivacaine 0.2% is used for regional infusions and can be combined with an opioid, such as fentanyl 2–4 µg/mL, for epidural infusion. Recommended maximum bolus doses and continuous infusion rates must be known. For ropivacaine, a single bolus of up to 3 mg/kg is allowed (to a maximum of 300 mg), whereas continuous infusion rates should not exceed 400 µg/kg/h
- adequate training of nursing staff to monitor the level of block in neuraxial techniques, haemodynamic parameters and for possible complications.

Within the previous context, the following blocks may be useful in patients:

- femoral nerve block for hip and femur injuries; 20–40 mL of 0.2% ropivacaine injected intermittently 8–12-hourly into the region of the femoral nerve immediately inferior to the inguinal ligament
- intercostal or paravertebral nerve blocks or catheters for thoracic and upper abdominal injuries or wounds; 20 mL of 0.2% ropivacaine injected into the region of appropriate intercostal nerve – a single injection site has been shown to cover multiple nerve root levels [77]
- brachial plexus or IV regional anaesthesia for isolated upper limb injuries or procedures (e.g. fracture manipulation)
- rectus sheath catheters or transversus abdominus plain (TAP) blocks for midline laparotomy incisions
- epidural analgesia for thoracic and abdominal pain (e.g. flail chest and pancreatitis)

Most commonly, regional analgesic techniques are instituted in theatre during major surgical procedures by anaesthetists. They provide valuable post-operative analgesia in intensive care.

Sleep

Although, outwardly, sedated patients resemble the sleep state, there are notable neurophysiological differences. Typically, critically ill patients have shorter periods of sleep, with a distinct reduction of slow-wave ‘deep’ sleep and rapid eye movement (REM) sleep. [78] Critically ill patients have poor sleep patterns due not only to their primary illness but a host of other factors, including:

- loss of the sleep–wake cycle after prolonged sedation
- pain
- invasive devices and monitoring
- the ICU environment
- nursing duties.

The importance of sleep disturbance in the critically ill outcome is unknown, but there is concern over its contribution to delirium.[79]

Much of the focus on improving sleep in critically ill patients relies on non-pharmacological measures, addressing the sleep environment and sleep hygiene of the patient. Pharmacological agents such as benzodiazepines may help patients to get to sleep quicker and wake less often but do not seem to improve the quality of physiological sleep.[79] Melatonin and melatonergic drugs (e.g. ramelteon and valdoxan) are increasingly used in ICU as a sleep aid. A natural hormone released from the pineal gland, studies demonstrate higher nocturnal melatonin levels promoting sleep and lower levels in patients with delirium.[80] Oral dosages between 2–5mg nocte are often used. Evidence in ICU to date has not demonstrated a significant benefit in improved sleep or delirium reduction.[81]

The Future

Research into sedation and analgesia in critically ill patients is intensifying. Areas in which future study is focusing include:

- patient-controlled sedation
- target-controlled infusions in intensive care
- automated/semi-automated sedation delivery systems[82, 83]

    algorithm, diagnosis, 330 *f*
    with highlighted premature capture beat, 332 *f*
    with obvious arteriovenous dissociation, 329 *f*
    patients with inducible, 351 *f*

Venturi principle, 504

Venturi-type masks, 504

Verapamil, 242 , 243 , 355

Vernakalant, 361

Vestibular-ocular reflex test, 112 *t*

Video-assisted thoracoscopic surgery, and blunt chest trauma, 932

Video consultation, 62–63

Video-laryngoscopy, 543–544 , 549–550

Vincristine, 1288

Viral meningitis, 766
  CSF examination, 766
  management, 766
  symptoms, 766

Viral prophylaxis, in lung transplantation, 1341

Viscoelastic haemostatic assays (VHA), 1269

Vital capacity, 465 *b* , 465

Vitamin C, for ARDS, 454

Vitamin D supplementation in critical illness, 709

Vitamin K, 630

Vitamin requirements, in critically ill patients, 625 *t*

Vocal cord palsy, in children, 1033

Volatile anaesthetic agents, 1359

Voltage-gated channels, 298

Volume-assured pressure support (VAPS), 524

Volume of distribution, 1350

Volume starvation, 479 *f* , 479–480 , 480 *f* , 480

Volumetric capnography, 464

Volutrauma, 448

von Willebrand disease, 1269 , 1277

von Willebrand factor, 1267

VOO pacing, 367–368

Vulnerable plaque, 264

VVI pacing, 368

W

Warfarin, 324 , 630
  combined with antiplatelet therapy, 324
  traumatic brain injury patients on, 913

Warm peripheries, septic shock in children and, 1069

Water
  bath humidifiers, 508
  diuresis, 825
  role in molecular acid-base transactions, 685

Water content
  as percentage of total body weight, 697 *t*
  of various tissues, 697 *t*

Water deprivation testing (WDT), 834 , 835 *f* , 835 *t* , 836 *f*
  AVP measurements and, 835
  induced hypovolaemia, 835
  interpretation of, 836 *t*
  limitations of, 835

Water metabolism, 696–697
  osmotic stimulation, 696–697
  renal action of antidiuretic hormone, 696 , 697

Water, regulation of, anti-diuretic hormone, 1049

Water requirements, 697 , 698 *t*

West Nile virus, 177 , 766

Whipple procedure, abdominal surgery and, 890

White thrombus, 264–265 , 265 *f* , 265

Whole genome sequencing, 143

Wide-complex tachycardia, 376 *f* , 376
  with pulse, 1123
  termination of, 330–331

Wilson disease, 653

Withdrawal syndromes, in sedation/analgesia in children, 1063

Wolff-Parkinson-White (WPW) syndrome, 305 , 327 *f*

Work of breathing, 436 , 437 , 472

World Allergy Organisation, in anaphylaxis, 1217

World Health Organisation (WHO), definition of obesity, 967

Wound
    botulism, 810
    debridement, 181

Wound ballistics, 1198
    determinants of
        amount of energy, 1198
        projectile effect, 1199

X

Xisomab, 1282

X-linked agammaglobulinaemia, 977

Z

Zanamivir, 516

Zero-order metabolism, 1351 , 1352 *f*

Zolpidem, 727–728

Zone of concussion, 1199

Zone of extravasation, 1199

Zygomatic fractures, 916

Zygomycoses, 159–160 , 159
